Abstract. Through the comparison of several regional-scale chemistry transport modeling systems that simulate meteorology and air quality over the European and North American continents, this study aims at (i) apportioning error to the responsible processes using timescale analysis, (ii) helping to detect causes of model error, and (iii) identifying the processes and temporal scales most urgently requiring dedicated investigations.

The analysis is conducted within the framework of the third phase of the Air Quality Model Evaluation International Initiative (AQMEII) and tackles model performance gauging through measurement-to-model comparison, error decomposition, and time series analysis of the models biases for several fields (ozone, CO, SO_2, NO, NO_2, PM_{10}, $PM_{2.5}$, wind speed, and temperature). The operational metrics (magnitude of the error, sign of the bias, associativity) provide an overall

sense of model strengths and deficiencies, while apportioning the error to its constituent parts (bias, variance, and covariance) can help assess the nature and quality of the error. Each of the error components is analyzed independently and apportioned to specific processes based on the corresponding timescale (long scale, synoptic, diurnal, and intraday) using the error apportionment technique devised in the former phases of AQMEII.

The application of the error apportionment method to the AQMEII Phase 3 simulations provides several key insights. In addition to reaffirming the strong impact of model inputs (emission and boundary conditions) and poor representation of the stable boundary layer on model bias, results also highlighted the high interdependencies among meteorological and chemical variables, as well as among their errors. This indicates that the evaluation of air quality model performance for individual pollutants needs to be supported by complementary analysis of meteorological fields and chemical precursors to provide results that are more insightful from a model development perspective. This will require evaluation methods that are able to frame the impact on error of processes, conditions, and fluxes at the surface. For example, error due to emission and boundary conditions is dominant for primary species (CO, particulate matter (PM)), while errors due to meteorology and chemistry are most relevant to secondary species, such as ozone. Some further aspects emerged whose interpretation requires additional consideration, such as the uniformity of the synoptic error being region- and model-independent, observed for several pollutants; the source of unexplained variance for the diurnal component; and the type of error caused by deposition and at which scale.

1 Introduction

The Air Quality Model Evaluation International Initiative (AQMEII; Rao et al., 2011) has been active since 2008 with the aim of promoting research on regional air quality model evaluation across the modeling communities of Europe and North America. It is coordinated by the European Joint Research Centre (JRC) and the US Environmental Protection Agency (EPA) and it has now reached its third phase, referred to as AQMEII3 hereafter. The experience gathered in the first two phases consisted of important advancement in the model evaluation research as well as establishing a large community of participating regional modeling groups. This has made AQMEII a natural candidate for collaborating with the Hemispheric Transport of Air Pollutants (HTAP) initiative. HTAP, a task force of the Long Range Transport of Air Pollutants (LTRAP) program acting within the United Nations Economic Commission for Europe (UNECE) program, relies on a community of global-scale chemical transport models to investigate the fate of air pollutants emitted in

the Northern Hemisphere and to determine the contribution of remote sources as well as their impacts on background concentration in different parts of the globe. HTAP is in its second phase and the activities undertaken during this second phase include coordinating simulations by both global- and regional-scale models. The regions of interest in the Northern Hemisphere are North America, Europe, and Southeast Asia. The regional-scale modeling component of this activity for Europe and North America is being coordinated by AQMEII, while the Asian component is being coordinated by MICs-ASIA (Model Intercomparison Study Asia). Global-scale models participating in HTAP are used by the AQMEII regional models as boundary conditions, and special attention has been given to the emission inventory to ensure that it is consistent between the global- and regional-scale simulations as described in Janssens-Maenhout et al. (2015). The activity described here relates to the evaluation of the base case scenario set up within the context of HTAP and AQMEII (Galmarini et al., 2017).

Following the simulation strategy developed over the first two phases of the AQMEII activity, two continental-scale domains were used in the exercise – one over Europe (EU) and one over North America (NA; Fig. 1). The modeling groups participating in AQMEII3 performed air quality (AQ) simulations over one or both of these domains. Each group was provided the same inputs for anthropogenic emissions and boundary conditions and was left the choice of the optimal configuration of the modeling systems, including meteorology, grid spacing, and natural emissions. To facilitate the cross comparison among models, the modeled outputs were successively interpolated to a common regular grid of 0.25° spacing over both continents. The comparison with observational data is performed by interpolating (or by simply taking the value from the grid cell where the monitoring sites are situated) the model values to prescribed observation stations (receptors) for surface measurements and at specified vertical heights for comparisons with measured profiles. As in the previous two phases of AQMEII, the ENSEMBLE system (Galmarini et al., 2012) hosted by the JRC was used to accommodate the data and to pair modeled to observational values in time and space to provide direct comparison and statistical analysis.

The model evaluation approach proposed and applied in this study combines aspects of operational and diagnostic evaluation as defined by Dennis et al. (2010). It makes use of the classical statistical indicators typically employed for operational evaluation based on the direct comparison with observations, but it also provides more indications on the processes contributing to model errors, which are the focus of diagnostic model evaluation (Solazzo and Galmarini, 2016). The data used in the analysis are not process specific but are ordinary time series of modeled and monitoring data, which are decomposed into four spectral components: ID (intraday), DU (diurnal), SY (synoptic), and LT (long-term), each determined by different physical and chemical
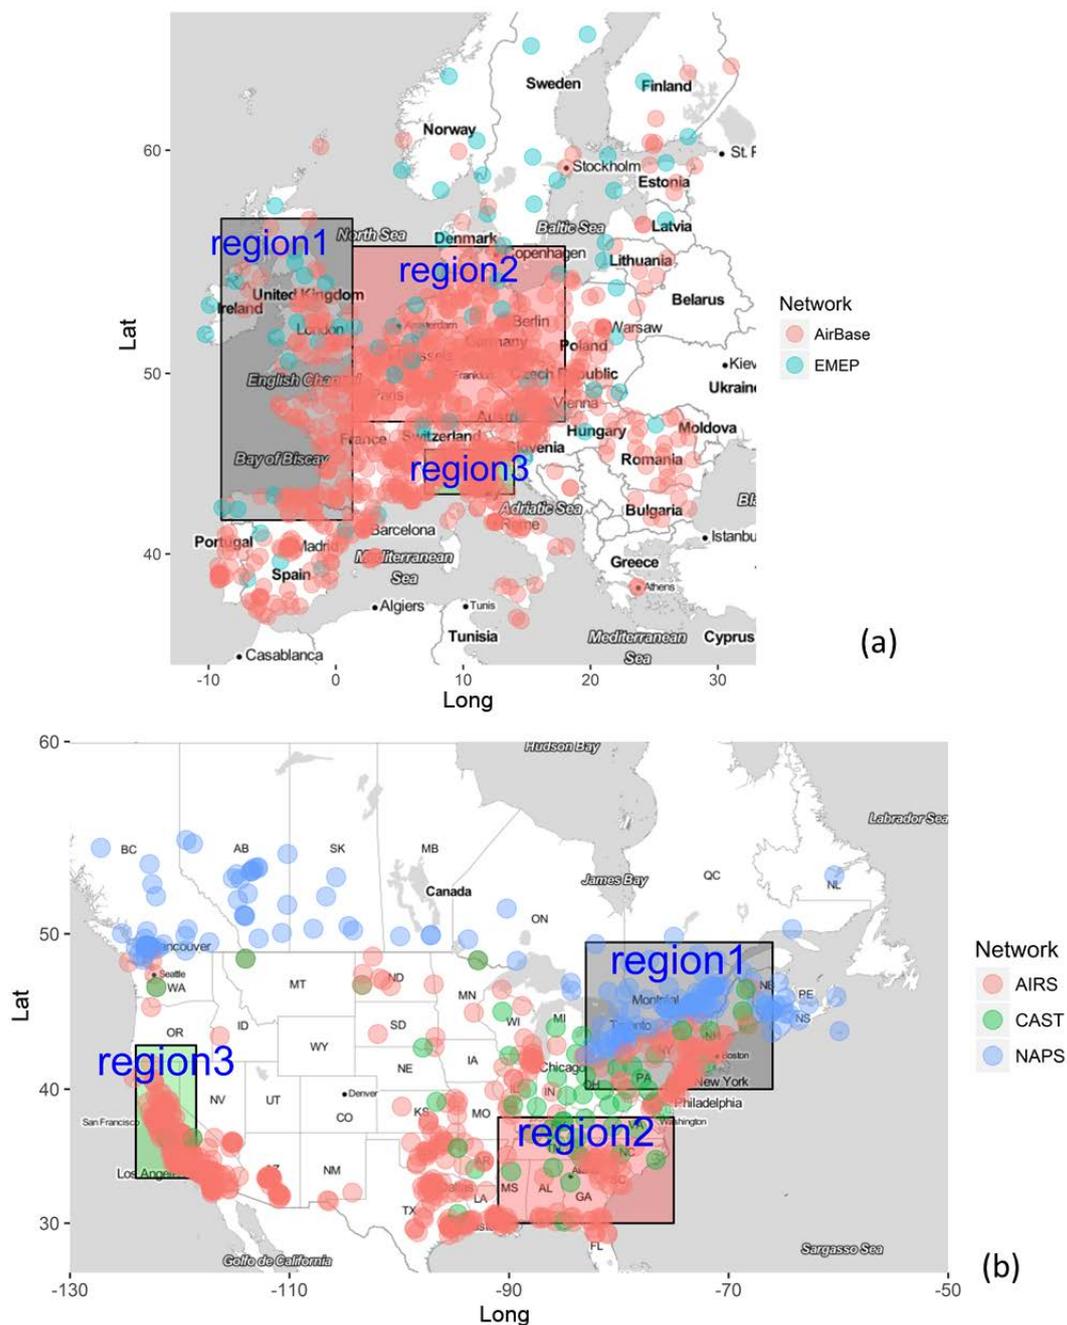

Figure 1. Subregions of the two continental domains **(a)** EU and **(b)** NA. Overlaid are the ozone monitoring stations classified based on the network.

processes (Rao et al., 1997). The error apportionment applied to each spectral component can provide indications on the possible sources of error. The scope of the diagnostic evaluation, as also highlighted by Gupta et al. (2009), is to move beyond the usual aggregate metrics that only offer a statistical interpretation towards the use of measures selected for the quality of the information they can provide to model developers and users.

The evaluation of the AQMEII3 suite of model runs is carried out for surface temperature (Temp), wind speed (WS) and wind direction (WD), and for the species CO, NO, NO_2, ozone, SO_2, PM_{10} (EU), and $PM_{2.5}$ (NA). Additional analyses making use of emission reduction scenarios (CO and NO) and vertical profiles (Temp, WS, ozone) are also presented.

The main scope of the analysis is to present a detailed overview of the skill of AQ models when compared with

measurements for several regulatory pollutants and their precursors. For each species, the error is

1. quantified seasonally for three subregions of each continent;

2. qualified in terms of bias, variance, or covariance type of error, and

3. apportioned to the atmospheric timescale, i.e., ID, DU, SY, or LT.

Given the large number of models and species for two continents and the screening scopes of this work, maps of model metrics at the individual receptor level are omitted. Instead, spatial averaging over preselected homogenous sets of measurement points is presented. Investigation of signal associativity through clustering analysis was performed for ozone and particulate matter (PM) (PM_{10} for EU and $PM_{2.5}$ for NA) over both continents following the procedure outlined by Solazzo and Galmarini (2015), allowing the detection of three subregions (hereafter referred to as EU1, EU2, EU3 and NA1, NA2, NA3; Fig. 1) where the LT and SY components showed robust clustering features. For consistency and to facilitate the interpretation of the results, the same subregions were adopted for all species.

The error breakdown, the time series decomposition, and the model and observational data used are presented in Sect. 2. In Sect. 3, the results of the error apportionment analysis are presented and discussed. A novel analysis based on the autocorrelation function (acf) of the LT component is presented in Sect. 4 for ozone. Conclusions are drawn in Sect. 5.

2 Methodology

The first step of the analysis is the spectral decomposition of the time series of modeled and observed species, as outlined in the methodology proposed in Solazzo and Galmarini (2016). Because each spectral component represents a range of processes in a specific spectral range, the deviation of the modeled from the observed spectral component is informative about the process(es) causing the error. The second step is to separate the mean square error (MSE) of each spectral component into its constituent parts: bias, variance, and covariance. These timescale-specific errors, expressed in terms of bias, variance, and covariance, then allow a more precise diagnosis of their cause.

2.1 Error break down

The MSE is the squared difference of the modeled and observed values:

$$\text{MSE} = E(\text{mod-obs})^2 = \frac{\sum_{i=1}^{n_t}(\text{mod}_i - \text{obs}_i)^2}{n_t}, \qquad (1)$$

where $E(\cdot)$ denotes expectation and n_t is the length of the time series. The bias is

$$\text{bias} = E(\text{mod-obs}), \qquad (2)$$

i.e., $\text{bias} = \overline{\text{mod}} - \overline{\text{obs}}$ (the overbar indicates temporal averaging). The following relationship holds:

$$\text{MSE} = \text{var}(\text{mod-obs}) + \text{bias}^2, \qquad (3)$$

where $\text{var}(\cdot)$ is the variance operator. By applying the known property of the variance for correlated fields,

$$\text{var}(\text{mod-obs}) = \text{var}(\text{mod}) + \text{var}(\text{obs}) - 2\text{cov}(\text{mod}, \text{obs}), \qquad (4)$$

the MSE can be expressed as

$$\text{MSE} = \text{bias}^2 + \text{var}(\text{mod}) + \text{var}(\text{obs}) - 2\text{cov}(\text{mod}, \text{obs}), \qquad (5)$$

where the covariance term (last term on the right-hand side of Eq. 5) accounts for the degree of correlation between the modeled and observed time series. Following Solazzo and Galmarini (2016), the MSE Eq. (5) is rewritten as

$$\text{MSE} = \left(\overline{\text{mod}} - \overline{\text{obs}}\right)^2 + (\sigma_{\text{mod}} - r\sigma_{\text{obs}})^2 + \text{mMSE}, \qquad (6)$$

where

$$\text{mMSE} = \sigma_{\text{obs}}^2(1 - r^2) \qquad (7)$$

is the minimum error achievable by an accurate (unbiased, $\overline{\text{mod}} = \overline{\text{obs}}$) and precise ($\sigma_{\text{mod}} = \sigma_{\text{obs}}$) modeling system ($r$ is the linear correlation coefficient). The first term on the right-hand side of Eq. (6) is the mean unconditional bias (how much the time-averaged modeled concentration is shifted with respect to the averaged observation); the second term includes variance and covariance types of error (due to differences in the amplitude and timing between the modeled and observed signals), and the MSE is the "unexplained" portion of the error, reflecting the amount of observed variance not accounted for by a linear model (Murphy, 1995). The mMSE type of error is caused by the variability of the observation not reproduced by the models, which includes incommensurability, noise, timing of the signal, and linearization of nonlinear processes, summarized by the coefficient of determination (Solazzo and Galmarini, 2016).

The decomposition in Eq. (6) includes all the operational metrics commonly adopted to evaluate the AQ models (bias, variance, correlation coefficient, and their sum, the MSE), and is thus suitable to be used as a compact estimator of model performance.

2.2 Spectral decomposition and error attribution

Spectral filtering was applied to the measured and modeled hourly averaged time series at the monitoring sites using the Kolmogorov–Zurbenko (kz) low-pass filter (Zurbenko, 1986). This allows the separation of different phenomena with distinct signals, such as long-term and short-term fluctuations in the observed and modeled time series (Rao et al., 1997). Applications of the kz filter to ozone have been described in a number of previous studies (Rao et al., 1997; Wise and Comrie, 2005; Hogrefe et al., 2000, 2003, 2014; Galmarini et al., 2013; Kang et al., 2013; Solazzo and Galmarini, 2015, 2016; Kioutsioukis et al., 2016).

The kz filter depends on the length of the moving average window m and the number of iterations k ($kz_{m,k}$) (k also indicates the level of noise suppression). Since the kz is a low-pass filter, the filtered time series consists of the low-frequency component, while the difference between two filtered time series (with different k and m) provides a band-pass filter. This latter property has been used in this study, as well as in a number of previous studies, to decompose the modeled and observed time series as

$$FT(S) = LT(S) + SY(S) + DU(S) + ID(S), \qquad (8)$$

where S is the time series of the species being analyzed and FT is the full (undecomposed) time series. Another possibility, not explored here, is to avoid the use of the band-pass property and use the kz filter to filter out the unwanted fluctuations directly from the FT time series.

The base-line component LT is the long-term component (periods longer than 21 days) and accounts for the temporal fluctuations determined by low frequencies, such as boundary conditions and seasonal variation in emissions and photochemistry. SY is the synoptic component containing fluctuations related to weather processes and precursor emissions occurring on scales between 2.5 and 21 days. The DU (diurnal) component accounts for fluctuations due to diurnal periodicity occurring on temporal scales between 0.5 and 2.5 days, and ID is the intraday component, accounting for fast-acting local-level processes (timescale less than 12 h; the spectral components have the same units as the undecomposed time series).

The decomposition Eq. (8) is such that the undecomposed time series is perfectly returned by the summation (or by the exponential product, see Appendix A for details) of the components. The band-pass nature of the SY, DU, and ID components is such that they only describe the processes in the time window the filter allows the signal to "pass". For instance, the DU component is insensitive to processes outside the range between 0.5 and 2.5 days.

Because the kz filter was originally developed to deal with ozone, the parameters k and m (Appendix A) are specifically tailored for ozone, taking into consideration its chemistry and life-time. In this study we have applied the kz filter to other

species and kept the same values for k and m for consistency and to facilitate the comparison of the results. Although some species (e.g., PM, CO, SO_2) may be less sensitive to day–night cycles than ozone, the distinction between DU and ID are still revealing of emission patterns like vehicular traffic and industrial activities, as well as diurnal variations in vertical mixing. Moreover, SY and LT are associated with transport and other weather processes common to all species.

Two aspects of the signal filtering with a profound impact on model evaluation are as follows:

1. The nonorthogonality of the spectral components is one of the major drawbacks of the signal decomposition. The relationship among the spectral components of Eq. (8) is nonlinear in m and k, and thus an orthogonal separation is not achievable (Rao et al., 1997; Kang et al., 2013). The leakage among components mixes together in different physical processes. Galmarini et al. (2013) found that the explained variance of the spectral components accounts for 75 to 80 % of the total variance, while the remaining portion of the variance is due to the interactions between the estimated components. The effect of these interactions on the error apportionment pursued in this study is outlined and quantified in Sect. 3. Other spectral techniques could be used, but either they do not guarantee the absence of signal leakage (e.g., anomaly perturbation method), require special treatment of missing data (e.g., wavelet transform method; Rao et al., 1997; Eskridge et al., 1997), are more convoluted (e.g., kz–Fourier transform), or simply have not been applied as frequently as the kz filter to air quality data (e.g., Bowdalo et al., 2016). Hogrefe et al. (2003) provided an exhaustive comparison among four techniques for separating different timescales in atmospheric variables (kz, kz–Fourier transform, wavelet transform, and elliptic filter) and concluded that they all gave qualitatively similar results in terms of the variance distribution among components and that no single filter outperformed the others for all applications.

2. The bias is calculated as the distance between the time-average modeled and observed time series. In such a time average sense, the baseline LT is the only biased component, containing the entire bias of the original time series. The other components are zero-mean fluctuations about LT and are unbiased. Although inaccuracy at each time step can also derive from the SY, DU, and ID components (Johnson, 2008), in this study the signal is taken as time-averaged over a finite period, and therefore the entire bias is apportioned to the baseline (LT) component.

Table 1. Participating Modelling systems and key features.

2.3 Models and observational data

Table 1 summarizes the modeling systems participating in AQMEII3. Four modeling groups produced outputs over NA and 12 modeling groups produced outputs over EU (although not all fields were made available by all groups). Sensitivity simulations performed by two groups, in which alternate emission inventories were used, raise the number of EU contributions to 14.

The "standard" emission inventories are those developed for the second phase of AQMEII for EU and NA and extensively described in Pouliot et al. (2015). For EU, the TNO-MACC-II (Netherlands Organization for Applied Scientific Research, Monitoring Atmospheric Composition and Climate) inventory of anthropogenic emissions for the year 2009 was used, while biogenic emissions (meteorology-dependent) were specifically calculated for the year of 2010 by several groups. Five modeling systems used the EDGAR-HTAPv2.2 emission inventory (Janssens-Maenhout et al., 2015), which complements the standard MACC inventory in regions outside EU (Table 1). The two inventories (MACC and HTAP) are approximately the same over the common part of EU (the standard MACC inventory does not cover North Africa, while it does cover eastern Europe, including Russia and Turkey) and only differ for regions outside European borders but within the domain boundaries, such as North Africa. Some discrepancies might exist among the two inventories (e.g., in the emissions from ships). Two EU modeling systems (CHIMERE and SILAM) made results available with both the MACC and the HTAP inventories. For CHIMERE, the MACC inventory over France and the UK was spatially redistributed considering national inventories (with higher spatial resolution), while for the other countries it was redistributed by considering point source locations, land use, and population. For processing the HTAP inventory, population was not used as a parameter for spatially distributing the emissions.

For the NA domain, the 2008 National Emission Inventory was used as the basis for the 2010 emissions, providing the inputs and datasets for processing with the Sparse Matrix Operator Kernel Emissions (SMOKE) processing system (Mason et al., 2012). Specific updates for the year of 2010 were made for several sectors, including mobile sources, power plants, wildfires, and biogenic emissions. Details are given in Im et al. (2015a, b) and Pouliot et al. (2015).

Typically, emission processors use annual emission total, while AQ models require hourly input values. Therefore, proxy variables and surrogate fields are used to spatially disaggregate the annual total and to allocate them temporally. The overall model accuracy heavily depends on the degree of similarity between the disaggregation of total emission and the true spatial and temporal distribution (Makar et al., 2014). Furthermore, the emissions for EU, being compiled on a country-wise basis, are affected by gaps and inconsis-

tency across borders, which require further processing and manipulation (Pouliot et al., 2015).

Emissions from lightning and volcanic sources are not contained in the EU and NA emission inventories since not all participating models include robust methods for estimating these emissions.

Chemical boundary conditions were provided by the Composition – Integrated Forecast System (C-IFS) model (Flemming et al., 2015), including ozone, NO_x, CO, CH_4, SO_2, NMVOCs, dust, organic matter, black carbon, and sulfate. Sea salt at the boundaries, although provided, was not used due to unrealistically high values.

2.3.1 Model features

This section presents the main features of the modeling systems participating in AQMEII3. Complementary information is provided in Table 1.

Three models (CHIMERE, SILAM, LOTOS-EUROS) used the meteorological inputs extracted by the ECMWF (European Centre for Medium-Range Weather Forecasts) operational archive, the Cosmo-CLM (CCLM from now on) model drove the Community Multi-scale Air Quality (CMAQ) simulations provided by the HZG (Helmholtz-Zentrum Geesthacht) institute, and all remaining models were driven by the meteorological fields generated by the WRF (Weather Research and Forecasting; Grell et al., 2005) model.

Bearing in mind that small changes in model configuration can produce significantly different outcomes (e.g., Herwehe et al., 2011), Table 2 summarizes the configuration of the WRF runs, detailing difference and commonalities. Without going into the detail on each parameterization, the differences among the planetary boundary layer (PBL) formulations (detailed review provided by Cohen et al., 2015) have a profound impact on the discussion of the error, especially (but not exclusively) on the diurnal scale. One of the main differences is the local vs. nonlocal closure of the PBL equations, indicating the depth over which the PBL variables influence the prediction at a given point. Nonlocal schemes offer more advantages than local ones, as the latter may not fully account for deeper vertical mixing associated with larger eddies, while nonlocal schemes are overall more accurate in simulating deeper vertical mixing in buoyancy-driven PBLs (Cohen et al., 2015). With reference to Table 2, the MYNN and MYJ (Janjic, 1994) are local schemes, the YSU (Hong et al., 2006) is a nonlocal scheme, and the ACM2 (Pleim, 2007) can be regarded as a hybrid scheme in that it incorporates local and nonlocal closures for potential temperature and velocity, resulting in more accurate vertical mixing.

The land surface processes are used to calculate the surface heat and moisture fluxes and strongly affect the prediction of temperature and humidity. RUC and NOAH land surface models have shown to behave similarly over the US (Jin at al., 2010), while Mooney et al. (2013) found that the NOAH

Table 2. Configuration of the WRF model by modeling group.

RRTMG: rapid radiative transfer method for global for solar and infrared radiation (Iacono et al., 2008). RRTM: rapid radiative transfer method for infrared radiation (Mlawer et al., 1997). Dudhia shortwave radiation scheme (Dudhia, 1989). YNN: Mellor–Yamada Nakanishi–Niino (PBL) scheme (Nakanishi-Niino, 2006). MYJ: Mellor–Yamada–Janjic (Janjic, 1994). YSU: Yonsei University PBL scheme (Hong and Lim, 2006). Grell–Freitas scheme for cumulus clouds (Grell and Freitas, 2014). Eta similarity surface layer (Janjic, 2002). KF2: Kain–Fritsch (Kain, 2004) scheme for cumulus parameterization. CAM scheme for long and short radiation (Collins et al., 2004). Morrison microphysics from Morrison et al. (2009). WSM3 microphysics scheme (Hong et al., 2004). WSM5: double moment 5–class scheme (Lim and Hong, 2010). WSM6: double moment 6–class scheme (Lim and Hong, 2010). MM5 similarity surface layer scheme (Zhang and Anthes, 1982). NCEP (National Centers for Environmental Prediction) FNL Operational Model Global Tropospheric Analyses. GFS: Global Forecasting System. FNL: Final (same as GFS but FNLs are prepared about an hour or so after the GFS is initialized so that more observational data can be used). NAM: North American Model. RUC Rapid Update Cycle (Smirnova et al., 2000). NOAH land-surface model (Tewari et al., 2004). ACM2: Asymmetric Convective Model with nonlocal upward mixing and local downward mixing (Pleim, 2007). Five-layer thermal diffusion (Dudhia, 1996). Pleim-Xiu: Plein and Xiu (2003).

surface scheme yields more accurate surface temperature results compared to RUC.

Six groups have operated the CMAQ model. The main differences among the CMAQ runs reside in the number of vertical levels (minimum of 23 for CMAQ4 up to 35 for CMAQ3 and WRF-CMAQ in NA) and horizontal spacing (from 12 km by WRF-CMAQ in NA down to 30 km by CMAQ3 and CMAQ4) and in the estimation of biogenic emissions. CMAQ4, CCLM-CMAQ, and WRF-CMAQ calculated biogenic emissions using the BEIS (Biogenic Emission Inventory System version 3) either as implemented in SMOKE v2.6 (https://www.cmascenter.org/smoke) or as implemented directly into CMAQ, while CMAQ1, CMAQ2, and CMAQ3 calculated biogenic emissions through the MEGAN model (Guenther et al., 2012). Moreover, the CCLM-CMAQ model does not include the dust module, while the other CMAQ instances use the inline calculation (Appel et al., 2013) and CMAQ1 uses the dust calculation previously calculated for AQMEII Phase 2. Finally, all runs were carried out using CMAQ version 5.0.2 except for CMAQ1, which is based on the 4.7.1 version. A series of known shortcomings of CMAQ v.5.0.2 are discussed in Appel et al. (2016) (and partially addressed in the new version 5.1 of the model), among which is the tendency to underestimate the vertical mixing during transition periods, with the net result of increasing the concentration of primary pollutants and reducing that of ozone as a consequence of more available NO_x.

Hereafter, more detailed information is provided for each modeling system.

The FMI (Finnish Meteorological Institute) has taken part with the ECMWF-SILAM system (ECMWF-SILAM_M and ECMWF-SILAM_H of Table 1, indicating the instances of the SILAM model that use the MACC and the HTAP emission inventory, respectively). SILAM v5.4 (Sofiev et al., 2015) was used, with meteorological input extracted from the ECMWF operational archives. The simulation included sea salt emissions as in Sofiev et al. (2011) (but not from the boundaries), biogenic VOCs (volatile organic compounds) emissions as in Poupkou et al. (2010), and wildland fire emissions as in Soares et al. (2015). The windblown dust is only included from the lateral boundary conditions. The volatility distribution of anthropogenic organic carbon (OC) was taken from Shrivastava et al. (2011). The gasphase chemistry was simulated with CBM-IV, with reaction rates updated according to the recommendations of International Union of Pure and Applied Chemistry (IUPAC) (http://iupac.pole-ether.fr) and the NASA Jet Propulsion Laboratory (JPL) (http://jpldataeval.jpl.nasa.gov). The secondary inorganic aerosol formation was computed with the updated DMAT scheme (Sofiev, 2000) and secondary organic aerosol formation with the volatility basis set (VBS; Ahmadov et al., 2012). Pressure- and latitude-dependent photolysis rates of the FinROSE model (Damski et al., 2007) are used and reduced proportionally to cloud cover below the clouds down to half the original value at full cloud cover. The SILAM model does not account for extra plume rise in addition to that prescribed by the emission profiles. A known deficiency of the SILAM version used in this study is the overestimation of ozone dry deposition.

The LOTOS-EUROS modeling system (Schaap et al., 2008, Sauter et al., 2012) was applied by TNO (the Netherlands Organisation for Applied Scientific Research), using version v1.10.1. The meteorological inputs were extracted from the ECMWF operational archives. For biogenic emissions the approach as described in Beltman et al. (2013) was used. Gas-phase chemistry is based on CBM-IV (modified

reaction rates; see Sauter et al., 2012), secondary inorganic aerosol (SIA) formation on ISORROPIA II (Fountoukis and Nenes, 2009), and for semivolatile species the VBS approach was used (Donahue et al., 2006; Bergström et al., 2012), with 100 % of the emitted OC mass in the four lowest volatility classes that are predominantly solid and an additional 150 % in the five higher volatility bins. Modeled terpene emissions were reduced by 50 % to limit their contribution to SOA (secondary organic aerosol) formation, which was found to be too high otherwise (Bergström et al., 2012). No NO_x emissions from soil were taken into account. The model includes pH-dependent conversion rates for SO_2 (Banzhaf et al., 2012), while only below-cloud scavenging is used for wet deposition. Mineral dust emissions were calculated online, including emissions from road resuspension and agricultural activities, according to Schaap et al. (2009). For sea spray the parameterizations by Monahan et al. (1986) and Martensson et al. (2003) were used. Photolysis rates are based on clear-sky photolysis rate by Roeth's flux algorithm (function of solar zenith angle; Poppe et al., 1996) and multiplied by an attenuation factor in case of clouds. The LOTOS-EUROS model does not account for extra plume rise in addition to that prescribed by the emission profiles. A specific feature of LOTOS-EUROS is that it only covers the lower 3.5 km of the atmosphere, with a static 25 m surface layer, a dynamic mixing layer and two dynamic reservoir layers. This makes the model relatively fast in terms of computation time but has implications for the vertical mixing of species for instances where the mixing layer rapidly changes in height.

The INERIS and CIEMAT institutes jointly applied the ECMWF-CHIMERE system. CHIMERE (version CHIMERE 2013) was run with meteorology provided by ECMWF IFS. Biogenic VOC emissions from vegetation and soil NO emissions were calculated with the MEGAN model (version 2.04; Guenther et al., 2006, 2012). Sea salt emissions inside the domain were calculated according to Monahan (1986). The windblown dust is only included from the lateral boundary conditions. CHIMERE uses the MELCHIOR2 chemical mechanism (Lattuati, 1997), and ammonium nitrate equilibrium was calculated with ISORROPIA (Nenes et al., 1999). Dry deposition is based on the resistance approach (Emberson 2000a, b) and both in-cloud and sub-cloud scavenging were considered for wet deposition.

WRF–WRF-Chem1 was applied by the University of L'Aquila (Italy). Version 3.6 of the Weather Research and Forecasting model with Chemistry (WRF-Chem) has been used, modified to include the new chemistry option implemented by Tuccella et al. (2015) that includes a better representation of the secondary organic aerosol mass in the simulation of direct and indirect aerosol effects, calculated as in Ahmadov et al. (2012). Here only direct effects were included in the simulation, for computational expediency. The model uses the RACM-ESRL gas-phase chemical mechanism (Kim et al., 2009), an updated version of the Regional

Atmospheric Chemistry Mechanism (RACM; Stockwell et al., 1997). The inorganic aerosols are treated with the Modal Aerosol Dynamics model for Europe (MADE; Ackermann et al., 1998). The parameterization for SOA production is based on the volatility basis set (VBS) approach. The aerosol direct and semi-direct effects are taken into account following Fast et al. (2006). Cloud chemistry in the convective updraft is modeled using the scheme of Walcek and Taylor (1986), while the aqueous-phase oxidation of SO_2 by H_2O_2 in the grid-resolved clouds is parameterized with the scheme used in GOCART (Goddard Chemistry Aerosol Radiation and Transport). Wet deposition from convective and resolved precipitation is included following Grell and Freitas (2014). The photolysis frequencies are calculated with the Fast-J scheme (Fast et al., 2006). Dry deposition and photolysis schemes were modified to take into account the effects of the soil snow coverage following Ahmadov et al. (2015). The anthropogenic emissions were taken from the TNO-MACC inventory for 2009 (Kuenen et al., 2014) and were adapted to the chemical mechanism used following the method of Tuccella et al. (2012).

WRF–WRF-Chem2 applied by the University of Murcia (Spain) relies on the WRF-Chem model. The following physics options were applied for the simulations: rapid radiative transfer method for global (RRTMG) long-wave and shortwave radiation scheme, Lin microphysics (Lin et al., 1993), the Yonsei University (YSU) PBL scheme (Hong et al., 2006), the NOAH land-surface model, and the updated version of the Grell–Devenyi scheme (Grell and Devenyi, 2002) with radiative feedback. Chemical options include RADM2 chemical mechanism (Stockwell et al., 1990), MADE/SORGAM aerosol module (Schell et al., 2001) including some aqueous reactions, and Fast-J photolysis scheme. The modeling domain covers Europe and a portion of North Africa.

Simulations of WRF-CAMx over EU were performed by RSE (Italy) using CAMx version 6.10 (Environ, 2014) with Carbon Bond 2005 (CB05) gas-phase chemistry (Yarwood et al., 2005) and the coarse–fine (CF) aerosol module. Input meteorological data were generated by WRF model version 3.4.1 (Skamarock and Klemp, 2008; Skamarock et al., 2008), driven by ECMWF analysis fields. Grid nudging of wind speed, temperature, and water vapor mixing ratio was employed within the PBL, with a nudging coefficient of $0.0003 \, s^{-1}$. WRF-Chem was adopted to predict GOCART dust emissions (Ginoux et al., 2001) along with the meteorology. The WRF-CAMx preprocessor (version 4.2; Environ, 2014) was used to create CAMx ready input files, collapsing the 33 vertical layers used by WRF into 14 layers in CAMx but keeping the layers up to 230 m above ground level identical. Biogenic VOC emissions were computed by applying the MEGAN emission model v2.04. Sea salt emissions were computed using published algorithms (de Leeuw et al., 2000; Gong, 2003).

Aarhus University (Denmark) applied the WRF-DEHM modeling system over EU and NA. The DEHM model used anthropogenic emissions from the EDGAR-HTAP database and biogenic emissions were calculated using the MEGAN model. The gas-phase chemistry module includes 58 chemical species, 9 primary particles, and 122 chemical reactions (Brandt et al., 2012). Secondary organic aerosols (SOA) were calculated following the two-product approach assuming that hydrocarbons undergo oxidation through O_3, OH, and NO_3 and for only two semi-volatile gas products (Zare et al., 2014). However, the module is simple because it does not include aging processes and further reactions in the gas and particulate phases (Zare et al., 2014).

WRF-CMAQ1 was applied by ITU (Istanbul Technical University) over EU. The Meteorology-Chemistry Interface Processor (MCIP) version 3.6 (Otte and Pleim, 2010) was used to process WRF output for CMAQ. The MEGAN v2.1 (Guenther et al., 2012) model was used to calculate the biogenic VOC emissions from vegetation, using surface temperature and radiation from MCIP output. CMAQ v4.7.1 (Foley et al., 2010) was configured with the CB05 chemical mechanism and the AERO5 module (Foley et al., 2010) for the simulation of gas-phase chemistry and aerosol and aqueous chemistry, respectively.

The WRF-CMAQ2 system was applied by Ricardo Energy & Environment (Ricardo E&E) over EU. It was configured using WRF v3.5.1 and CMAQ v5.0.2. The CMAQ model adopted the CB05-TUCL chemical mechanism (Whitten et al., 2010; Sarwar et al., 2011) and the AERO6 three-mode aerosol module (Appel et al., 2013). MCIP version 4.2 was used to process WRF output for CMAQ. The MEGAN v2.0.4 model was used to calculate the biogenic VOC emissions from vegetation, using surface temperature and radiation from MCIP output.

The WRF-CMAQ3 modeling system was applied by the University of Hertfordshire and utilized the uncoupled version of the WRF v3.4.1 model and CMAQ v5.0.2. The results from WRF simulations were preprocessed for CMAQ using MCIP version 3.6 (Otte et al., 2005). In the CMAQ model, the gas-phase chemical mechanism was based on Carbon Bond chemical mechanism version 5 (Foley et al., 2010) with updated toluene and chlorine chemistry (CB05-TUCL), and the aerosol chemical reaction was treated with AERO6 module. The biogenic emissions were derived from MEGAN.

The WRF-CMAQ4 simulation was performed by Kings College (UK) using CMAQ v5.0.2 (Byun and Schere, 2006), with CB05 chemical mechanism that included aqueous and aerosol chemistry. The CMAQ model is driven by meteorological fields from WRF v3.4.1. The anthropogenic emissions for most of the model domain are from MACC and the missing information was filled with the emissions provided by EDGAR/HTAP. The biogenic emissions were estimated using the BEIS3 model. The dust and sea salt (Gantt et al., 2015) emissions were generated using CMAQ inline modules.

HZG used the COSMO-CLM meteorological model to drive the CMAQ model. For AQMEII3, CMAQ version 5.0.1 was used, with the CB05-TUCL scheme and the multi-pollutant aerosol module AERO6. CMAQ was run using the optional in-line calculation of dry deposition velocities. Wet deposition processes include in-cloud and sub-cloud scavenging processes. All atmospheric parameters were taken from regional atmospheric simulations with the COSMO-CLM (CCLM) mesoscale meteorological model (version 4.8) for the year 2010 (Geyer, 2014) using National Centers for Environmental Prediction (NCEP) forcing data employing a spectral nudging method for large-scale effects (Kalnay et al., 1996). CCLM is the climate version of the regional-scale meteorological community model COSMO (Rockel et al., 2008; Steppeler et al., 2003; Schaettler et al., 2008). CCLM uses the TERRA-ML land surface model (Schrodin and Heise, 2001), a turbulent kinetic energy (TKE) closure scheme for the PBL (Doms et al., 2011), cloud microphysics after Seifert and Beheng (2001), the Tiedtke scheme (Tiedtke, 1989) for cumulus clouds, and a long-wave radiation scheme following Ritter and Geleyn (1992). The meteorological fields were processed afterwards to match the $24 \times 24\,km^2$ CMAQ grid using the LM-MCIP preprocessor. The emission input for CCLM-CMAQ is based on the EDGAR HTAPv2 database, interpolated to the CMAQ model grid and aggregated following the SNAP emission sector nomenclature. Sector-specific hourly temporal profiles and speciation factors of PM and VOC species were applied by the SMOKE for Europe emissions model (Bieser et al., 2011a). The temporal profiles used were fixed monthly, weekly, and diurnal profiles. Biogenic emissions and NO emissions from soil were calculated using the BEIS3 model. Sea salt emissions were calculated in-line by CMAQ, including sulfate emissions based on an average sulfate content of 7.7 %. Finally, fixed vertical profiles were applied for each source sector (Bieser et al., 2011b).

The WRF-CMAQ system applied over NA by the US EPA was configured using WRF v3.4 and CMAQ v5.0.2 (Appel et al., 2013; see also Foley et al., 2010 and Byun and Schere, 2006). The options used in these WRF and CMAQ simulations are identical to those described in Hogrefe et al. (2015), except that the current simulations were performed in off-line rather than two-way coupled mode. Temperature, wind speed, and water vapor mixing ratio were nudged above the PBL following the approach described in Gilliam et al. (2012). Soil temperature and moisture were nudged following Pleim and Xiu (2003) and Pleim and Gilliam (2009). The $NO_2\,/\,NO_x$ split applied during SMOKE emission processing varies for different categories. For many categories the assumed split is 90 % NO / 10 % NO_2, but for mobile sources the split varies for different types of vehicles and different emission processes.

Ramboll Environ used CAMx (version 6.2, Ramboll Environ, 2015) for simulations over NA, with a CB05 chemical mechanism for the gas phase. Biogenic emissions were ob-

tained from the MEGAN model version 2.1 (Guenther et al., 2006). Meteorological fields were produced by the US EPA using the WRF model and they were reformatted using the WRF-CAMx preprocessor to be readily used by the CAMx model.

2.3.2 Observational data used

The observational data used in this study are the same as the dataset used in second phase of AQMEII (Im et al., 2015a, b) and was derived from the surface air quality monitoring networks operating in EU and NA. In EU, surface data were provided by the European Monitoring and Evaluation Programme (EMEP, 2003; http://www.emep.int/) and the European Air Quality Database (AirBase; http://acm.eionet. europa.eu/databases/airbase/). In NA observational data were obtained from the NAtChem (Canadian National Atmospheric Chemistry) database and from the Analysis Facility operated by Environment Canada (http://www.ec.gc.ca/ natchem/). For the purposes of comparing the models against observations, only stations with data completeness greater than 75 % for the whole year and elevation above ground below 1000 m were included in the analysis. Stations with continuous missing records for periods longer than 15 days were removed from the dataset. No imputation on missing values was performed.

In addition, we also make use of vertical profiles of ozone, temperature, and wind speed data measured by ozonesondes and extracted from the World Meteorological Organization (WMO) World Ozone, and Ultraviolet Radiation Data Centre (Toronto, Canada) and made available to the AQMEII community. These measurements report vertical profiles of ozone at several vertical levels. Further details on these data are given in Solazzo et al. (2013).

Time-averaged statistics were calculated after the spatial aggregation of the modeled and observed time series over the subregions shown in Fig. 1 and prior to the spectral decomposition (the original time series were spatially averaged first and then this spatial average time series was spectrally decomposed). As noted in the introduction, unsupervised hierarchical clustering was used to determine subregions where the LT and SY components showed similar characteristics – spatial averaging within these subregions was carried out due to the similarity of the observation data within these regions, implying they will experience common physical and chemical characteristics. Errors due to the heterogeneity induced by country-specific emission profiles (in EU) are therefore included in the DU component. As a consequence of the spatial averaging, the relative importance of the ID component is likely reduced, since the ID fluctuations are highly variable in space (Hogrefe et al., 2014). Furthermore, no land-use type filtering was applied to the stations used for evaluation. While this choice limited impact on the SY and LT components (Solazzo and Galmarini, 2015; Galmarini et al., 2013), the DU components of some species (such as ozone, PM, and

NO_x) might be strongly influenced by the vicinity of urban stations to emission sources.

Details of the modeled regions and number of receptors are reported in Table 3.

3 Results

The analyses presented in this section focus on evaluating the performance of the models. The accuracy of the spectral components is first analyzed in terms of the RMSE and quantified on a seasonal basis. The season most affected by error is then further investigated by applying error apportionment (Eq. 6) to the spectral components. Results are presented for one subregion only (results for the other subregions are included in the Supplement).

The combination of the spectral decomposition and error apportionment has the effect of neglecting the error associated with the cross components (12 spectral interaction terms; see Solazzo and Galmarini, 2016 for details) since the apportionment only deals with the error of the "diagonal" components LT, DU, SY, and ID. The reason is that while the contribution of the cross components to the overall error can be quantified, the associated time series needed to carry out the apportionment analysis cannot. The neglected part of the error is quantified in Table S1 in the Supplement. In some instances, such a portion can be as high as 20 % of the total error for ozone.

The tables summarizing the operational statistics (MB is mean bias, r is Pearson's correlation coefficient, and RMSE is root mean square error) are reported in the Supplement and were calculated using the openair package (Carslaw and Ropkins, 2012).

3.1 Meteorological drivers: temperature, wind speed, and wind direction

3.1.1 Wind speed and temperature

The RMSE for surface temperature and wind speed is reported in Figs. 2 (EU) and 3 (NA). For EU (Fig. 2a), the RMSE of the full (i.e., not spectrally decomposed and denoted as FT in the plots) time series of temperature for the entire year is, on a seasonal average, on the order of ∼ 0.5–2 K (but often exceeding 3 K in EU3), with higher values typically occurring in spring and winter. The CHIMERE and SILAM models (both directly driven by the global meteorological fields provided by ECMWF) report the smallest error in EU1 and EU2, while the WRF-Chem2 model has the largest error in all subregions (up to ∼ 5 K for EU3 in summer), which is largely caused by the unusually large error in the SY component when compared to other models. The RMSE of the LT component resembles the behavior of the full time series, with the highest error in spring and winter (on average). The RMSE of the SY component is below ∼ 2 K (slightly higher in EU3) except for WRF-Chem2,
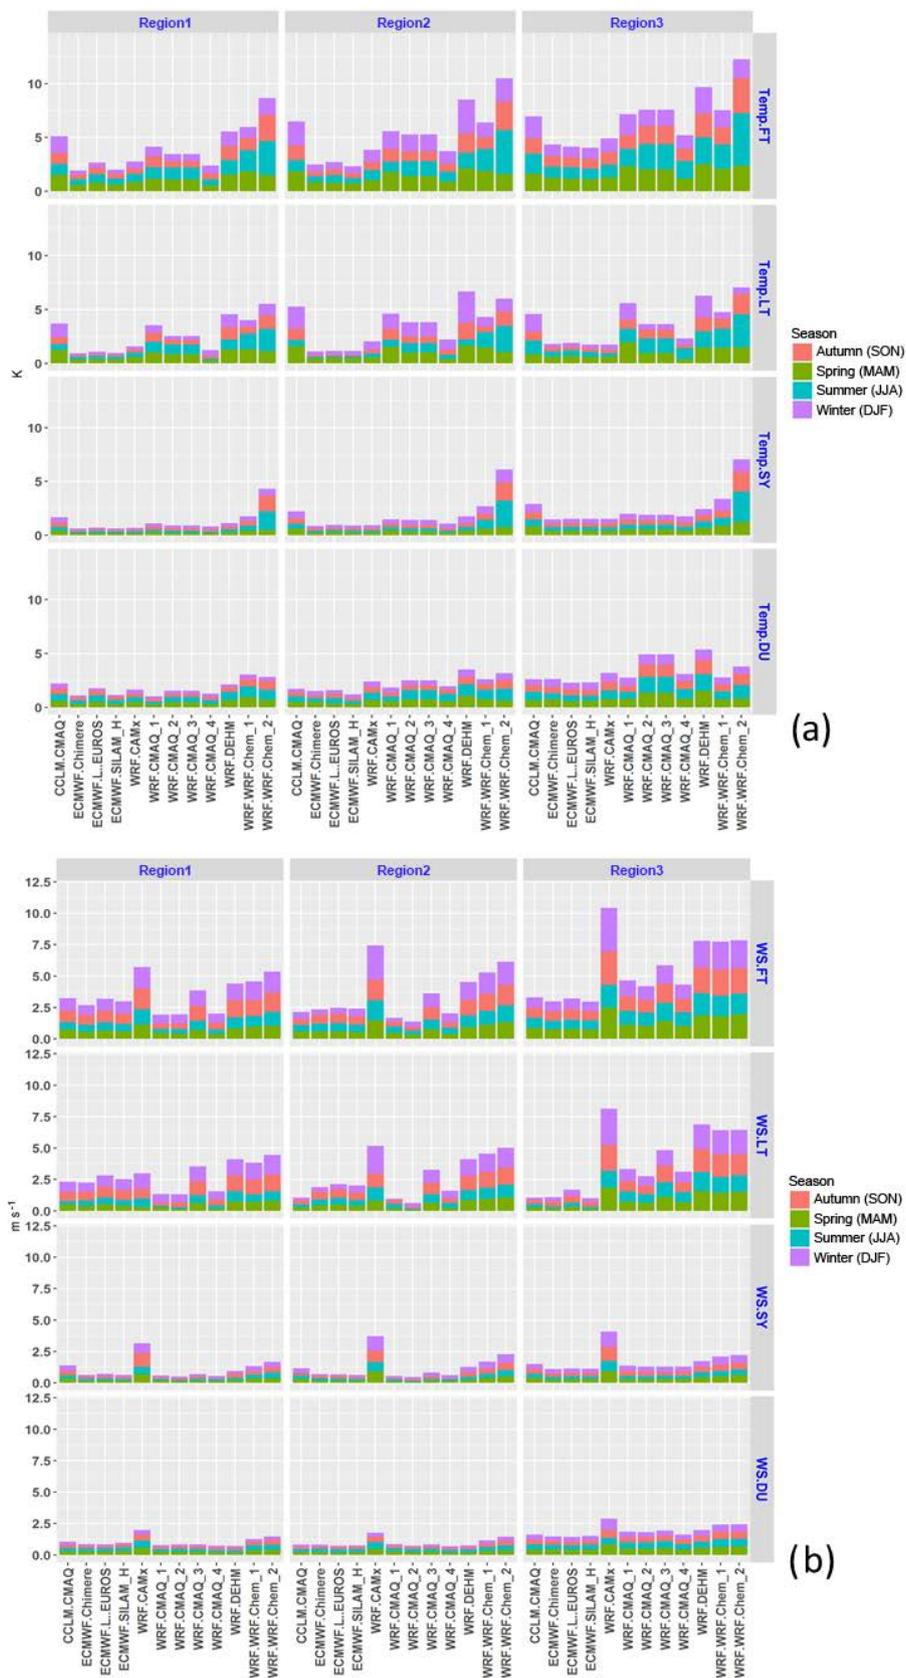

Figure 2. RMSE for **(a)** temperature and **(b)** WS in Europe.
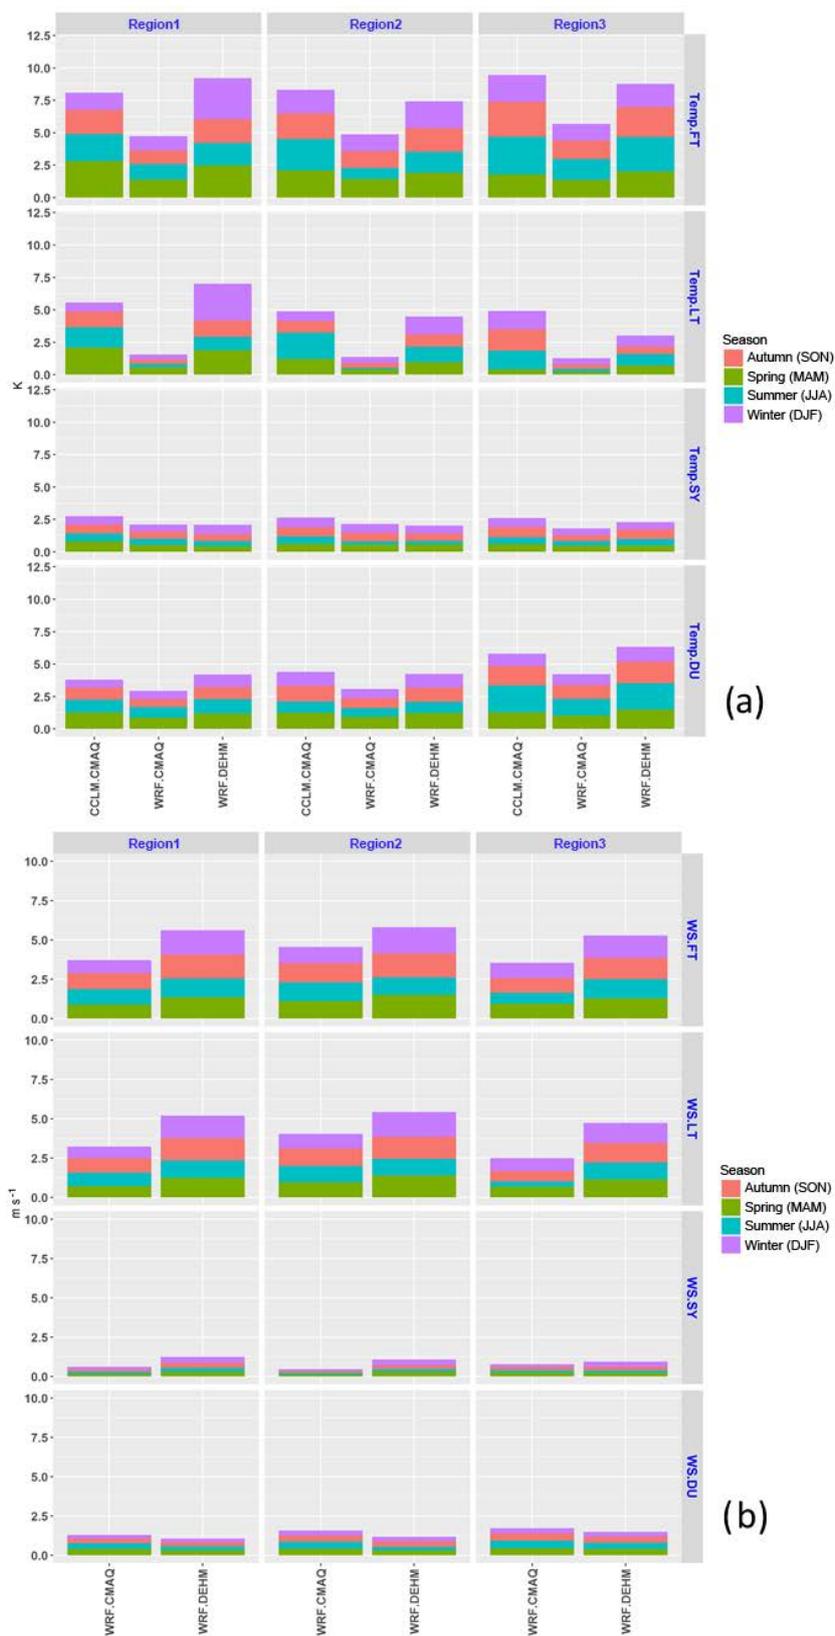

Figure 3. RMSE for **(a)** temperature and **(b)** WS in North America.

Table 3. Extension of the subregions and number of receptors used in the analysis.

	EU1/NA1 42–57.2° N; −9–1.3° W/ 40–49.5; −83 to −66° W	EU2/NA2 47.5–56° N; 1.3–18° W/ 30–38° N; −91 to −75° W	EU3/NA3 43.5–46° N; 7–14° W/ 33.5–43; −124 to −118.5° W	EU/NA 30–65° N; −10–33W/ 26–51° N; −125 to −55° W
Ozone	134/165	352/63	120/93	972/667
CO	32/29	91/8	70/12	418/103
NO (EU)	27	367	161	836
NO_2	149/97	529/21	176/54	1390/340
SO_2	96/69	296/3	55/3	865/141
PM_{10} (EU)	47	347	2	619
$PM_{2.5}$ (NA)	89	9	22	226
WS	168/229	305/245	5/59	827/1721
Temp	168/232	305/243	5/46	830/1546

whereas the DU component shows a more marked regional dependence, with the EU3 subregion reporting, on average, approximately 50 % higher seasonal error than the other two subregions; this is more pronounced in summer. The correlation coefficient is higher than 0.90 for the majority of models and spectral components (Table S2).

The bias for temperature is predominantly negative (model underestimation) for all EU models and subregions, except for WRF-CMAQ4 in EU3, where the model overestimates the measured temperature in summer and winter. According to Katragkou et al. (2015), cold bias during the summer by WRF is typically related to the CAM radiation scheme, and in general the land surface model is pivotal in determining the sign and amount of bias (Mooney et al., 2013). In particular, the combination of NOAH surface scheme and CAM radiation model seems more prone to cold bias.

For NA (Fig. 3a) the temperature RMSE of the WRF-DEHM and CCLM-CMAQ models (peaking in winter and autumn) is ~ 1–1.5 K larger than the WRF-CMAQ model. The error of the SY component is ~ 0.5 K, while that of the DU component is significantly higher (between 0.5 and 2 K). The WRF-CMAQ model has a small bias (LT error small) so that the overall error is dominated by the error in the DU component. The bias is negative for the WRF-DEHM model in all subregions and has the same sign for CCLM-CMAQ and WRF-CMAQ, i.e., negative in spring and positive in the other seasons (although for NA2 and NA3 WRF-CMAQ reports a slightly negative bias in winter also, Table S2).

The RMSE of the surface WS for EU shows large model-to-model variability, more markedly for the LT and SY components (all subregions, Fig. 2b), whereas the error of the DU component is more evenly distributed across models (and significantly higher in EU3, where low wind speed conditions are predominant). Although the meteorological fields are assimilated within the models (either from NCEP or from ECMWF, see Table 2), there are profound differences in the way these fields are ingested and interpolated to the model grid, as well as differences in the parameterization of the

boundary and surface layer, which impact the modeled wind speed and temperature. For example, the two instances of WRF-Chem applied the assimilation of the meteorological fields (wind speed, temperature, and relative humidity) of global meteorological fields only above the PBL, whereas other models (e.g., WRF-CAMx) assimilated the global data also within the PBL. For the models directly driven by the global fields, (e.g., SILAM, CHIMERE) the seasonal error for WS (~ 0.5–1 m s^{-1}) and temperature (0.4–1.2 K; Fig. 2a, b) can be considered as the uppermost limit the accuracy of the models can achieve. Thus, the assimilation and interpolation method errors (which are specific to the configuration of the meteorological model) can add more than 1.5 K and 2 m s^{-1} to the total error.

The full WS time series of the WRF-DEHM, WRF-Chem1 and WRF-Chem2 models report the largest error (in excess of 1.5 m s^{-1}), and the WRF-CAMx model even reports up to 2.4 m s^{-1} in winter (all subregions, Fig. 2b). On average, the remaining models have an error of 0.5–0.7 m s^{-1}. Most of the error is apportioned to the LT component, with the SY and DU below 0.3 m s^{-1} (except for WRF-CAMx and the other models mentioned above).

The WS bias is positive for all models (model over-prediction), for all seasons and subregions (only exception is the CCLM-CMAQ model, biased low during spring and summer in EU3 and WRF-CMAQ2 during the summer in EU1). The correlation coefficient is above 0.9 for the majority of models and components (except for the models affected by large errors such as the WRF-CAMx model). In general, r is slightly lower in EU3 and is at the maximum for the SY component (Table S3).

For NA (Fig. 3b), the WRF-DEHM model reports an error of ~ 1–1.2 m s^{-1} during all seasons and in all subregions, while the error of the WRF-CMAQ model ranges between 0.45 and 0.75 m s^{-1} for all seasons and subregions. The error of the SY and DU components is small (below 0.3 m s^{-1} for each season) for both models. Both models are biased high

456	57	2–5 per month; 25 in July	17:00–18:00
457	75	Year (2–5 per month; 18–20 in May–June)	23:00–00:00
458	71	Year (3–8 per month; 20 in July)	23:00–00:00

(all instances) and the correlation coefficient is on the order of ∼ 0.9 or above (Table S3).

3.1.2 Vertical profiles of wind speed and temperature

Vertical profiles of mean bias for temperature and WS are reported in Figs. 4 to 7. The modeled profiles were evaluated using ozonesonde measurements. The frequency and local time of the launches are summarized in Table 4. The launches in EU predominately occurred during daylight hours, whereas for NA measurements are also available for nighttime and late afternoon. The sign and magnitude of the bias are informative about error in the PBL processes, which will help discussion on the error of the modeled pollutants (Sect. 3.3).

The bias for temperature in EU ranges between −3 K (CCLM-CMAQ at station 308, Fig. 5) and +2 K (WRF-CMAQ4 at station 308 and SILAM at station 156) at the surface. In most cases the temperature bias profiles fluctuate around zero (station 053, located between EU1 and EU2; station 043; station 242 in EU2; and partially station 316 in EU2), whereas for some stations the bias keeps the same sign throughout the troposphere, negative for station 156 (launches at 10:00–12:00 LT) and positive for station 099 (early morning launches). The difference in altitudes (491 the former and 1000 m a.s.l. the latter) and the complex terrain of the alpine region might also be responsible for the large model differences at these two (relatively close) stations.

Vertical profiles of temperature in NA (Fig. 6) show strong surface bias (negative) at station 021 and 457 (both close to the western border of the domain) for both models. At sta-

tion 021 (data collected under daylight conditions) the bias becomes positive and small in magnitude above the PBL, whereas at station 457 (data collected under nighttime conditions) the bias keeps the same sign throughout the troposphere. At the other stations, the bias within the PBL is overall small and either positive (107, 456) or slightly negative (stations 458, 338).

Bias profiles for WS at eight ozonesonde stations in EU (Fig. 4) show a tendency of overestimation in the PBL and of underestimation above ∼ 1000 m, although there are some exceptions for different models and/or launching stations. The WRF-Chem1 has the largest positive bias at all sites, with the bias staying positive well above the PBL at all stations in contrast with all other models (WRF-Chem1 model adopted the nudging of meteorological fields only above the PBL and only during the first 12 h of meteorological spin-up, while for the other WRF instances the nudging is active during the entire run). WS overestimation by WRF-Chem is a known concern (e.g., Tuccella et al., 2012; Jimenez and Dudhia, 2012; Mass and Ovens, 2011) and it is likely to have a major impact on the dispersion of pollutants. Similar to EU, the WS bias profiles in NA are biased high near the surface (except for the station 338 and partially station 021, Fig. 6). Above the PBL the tendency is to underestimate the WS (up to ∼ 1.5 m s^{-1}), although less dramatically than in EU. Because both NA models are driven by WRF for meteorology, the WS profiles are alike and the magnitude of bias is very similar.
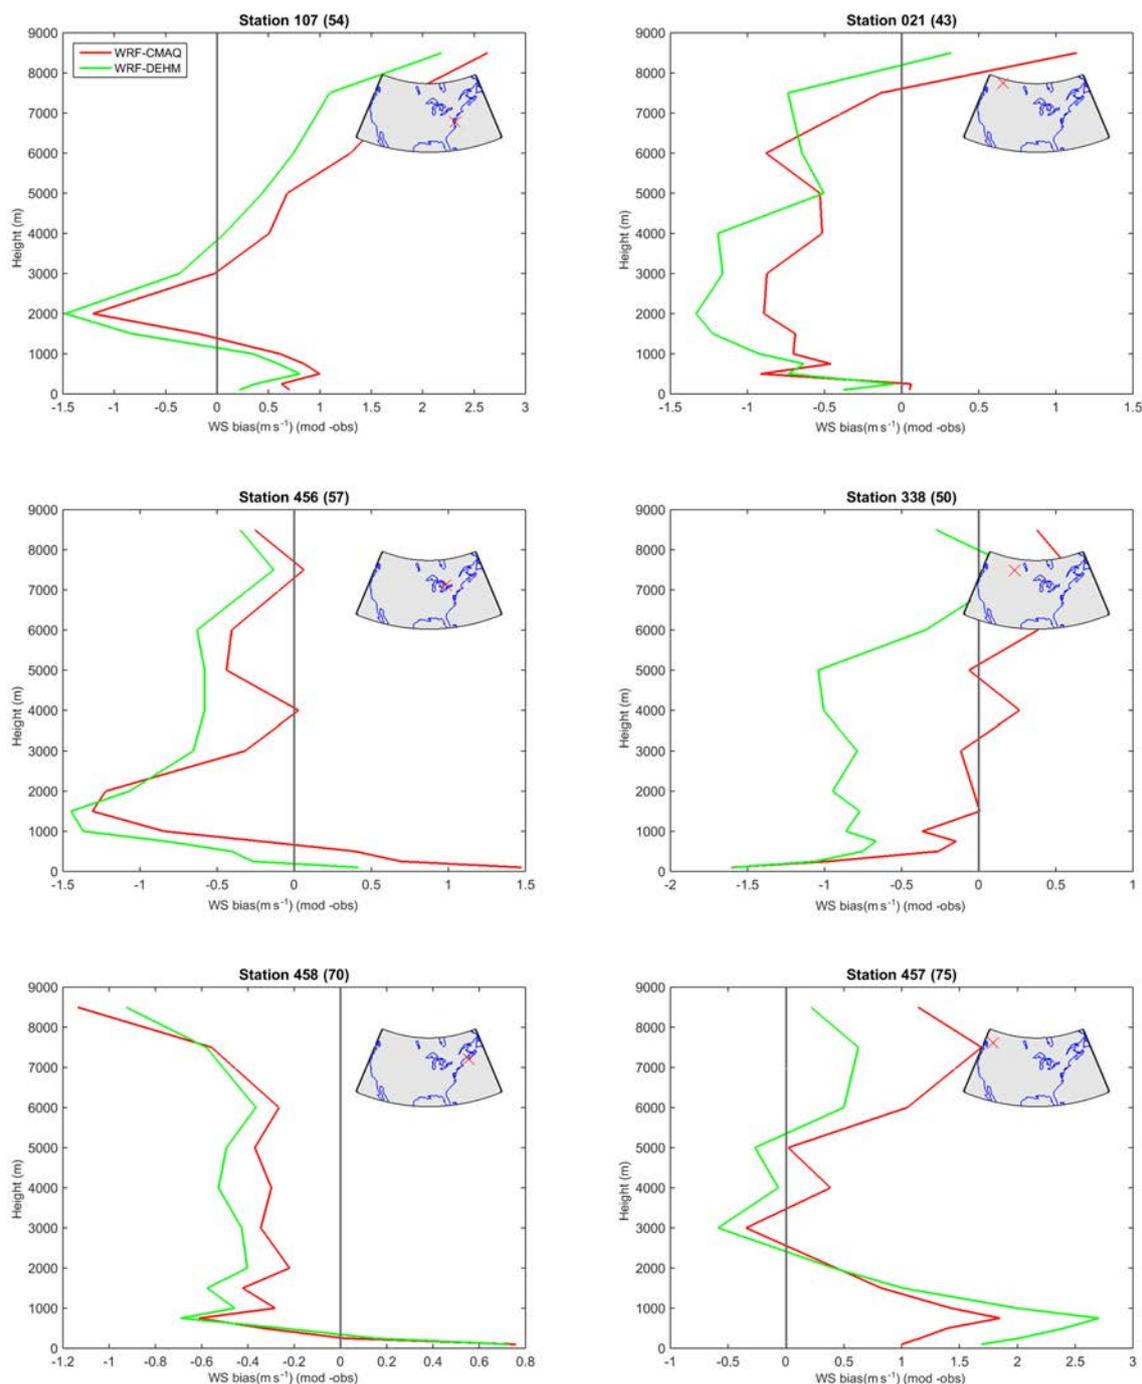

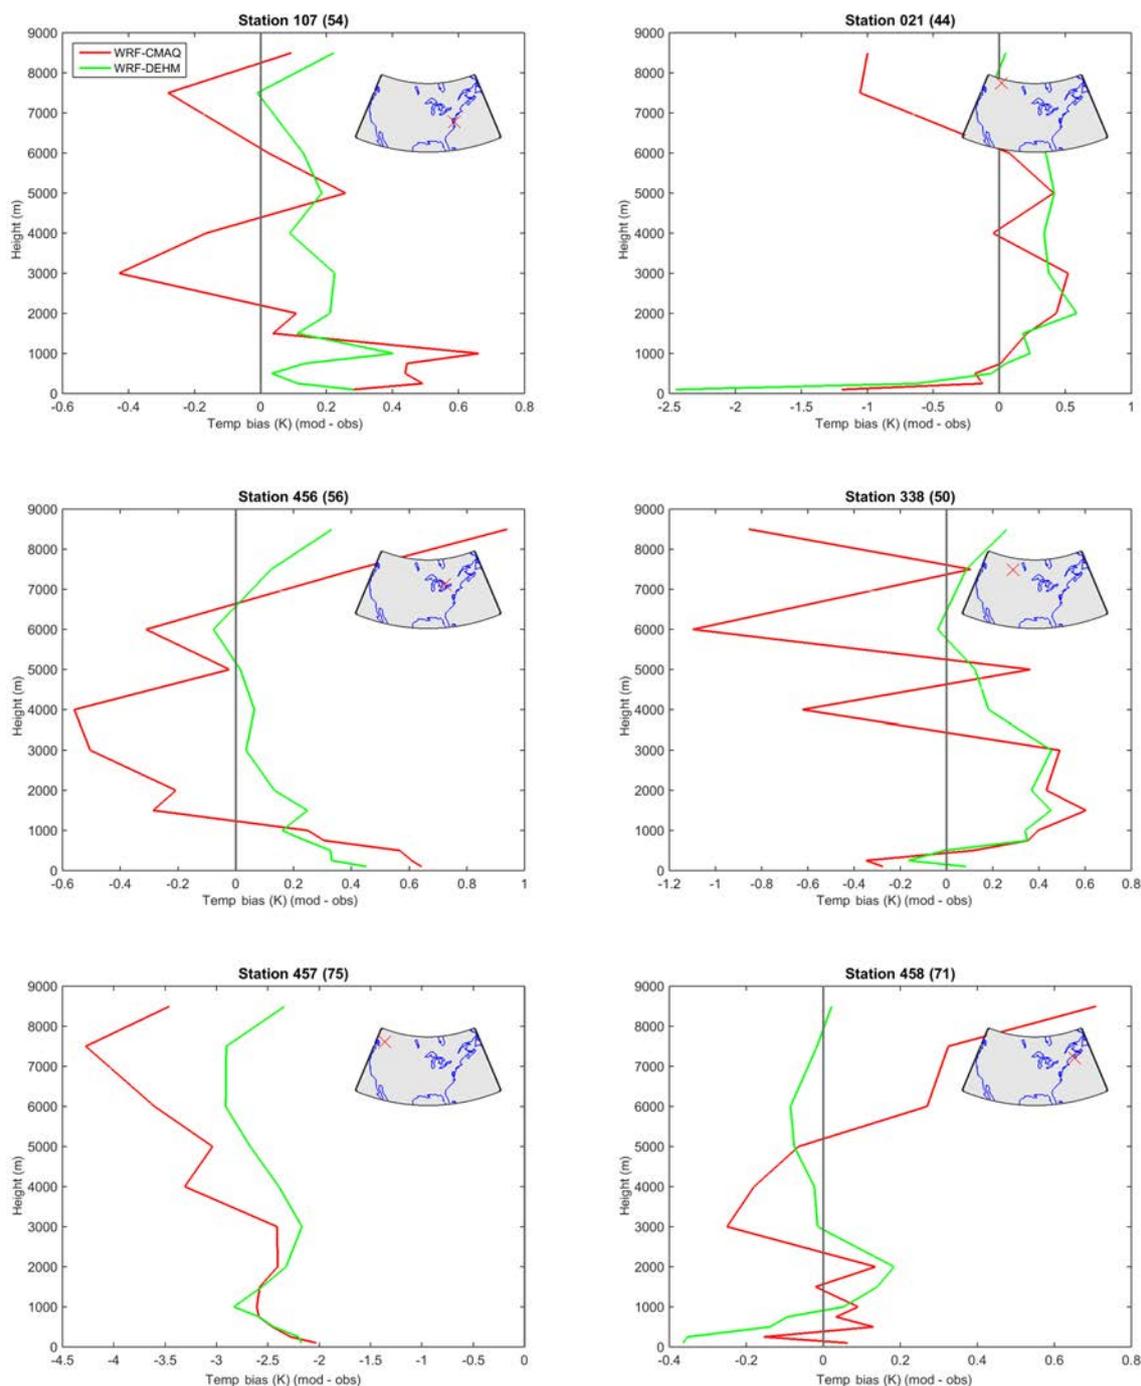

Figure 6. Mean bias (model–observations) for the vertical profiles of wind speed measured by ozonesondes launched from the North American locations indicated in the inset map of each panel. The number of hourly profiles available for each site is reported in parentheses at the top of each panel.

3.2 Wind direction

The spatial and temporal distributions of WD are reported in Fig. 8. The boxes summarize the temporal and spatial variability of the WD values at the receptors of each subregion (no averages were applied). For EU1 (Fig. 8a), the median

of all models but WRF-CAMx is within ±5° of the observation, similar to EU2. The modeled 22th and 75th percentiles are also in line with the observations in these two subregions (the CCLM model predicts slightly larger variability).

The EU3 subregion is topographically more complex, and the analysis is based on four stations with only 55 % data va-

Figure 7. Mean bias (model–observations) for the vertical profiles of temperature measured by ozonesondes launched from the North American locations indicated in the inset map of each panel. The number of hourly profiles available for each site is reported in parentheses at the top of each panel.

lidity over the entire period. Southern winds are predominant (based on the observation), while the models show large variability and even several instances of WRF (but not all) and ECMWF data tend to underpredict the median value. The only two models that overpredict the median observed value are WRF-CMAx and WRF-CMAQ1; both also apply grid

nudging within the PBL along with WRF-CAMQ4, which shows a slight underestimation however.

Results for NA in Fig. 8b show that the modeled WD follows the same distribution as the observed WD, with some excess (or deficiency) of variability by CCLM in NA1 (also the median value is also slightly underestimated) and in NA3.

Wind direction (deg)
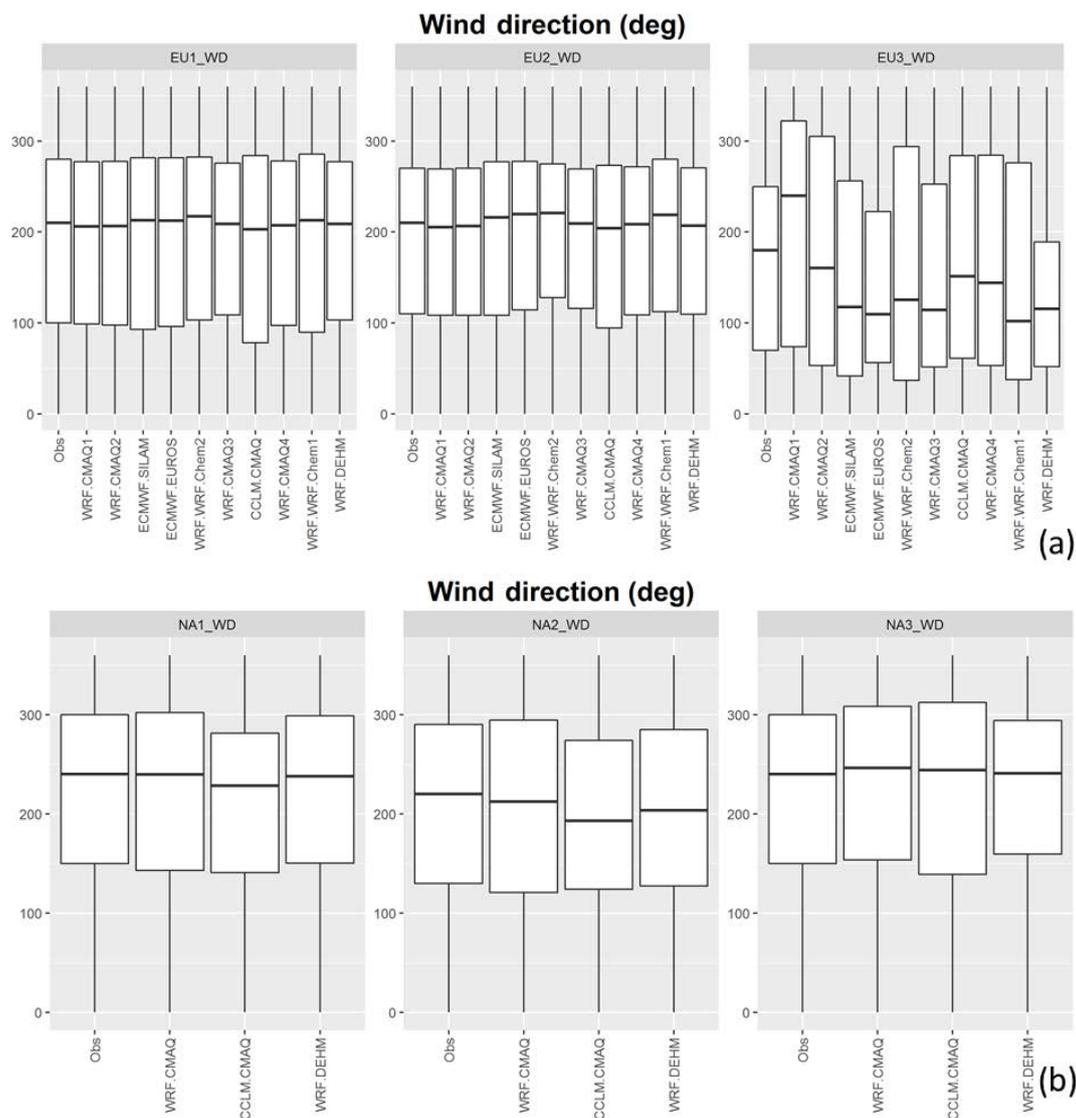

Wind direction (deg)

Figure 8. Spatial and temporal variability of the wind direction for **(a)** EU and **(b)** NA for the full year 2010. The boxes extend between the 25th and 75th percentiles of the total distribution. The whiskers extend from the minimum to the maximum values.

In NA2, all models tend to underestimate the observed median value (CCLM by $\sim 20°$), indicating a modeled abundance of southerly rotated winds. The WRF-CAMx model for NA, although not reported, uses the same meteorology as WRF-CMAQ and therefore the same WD distribution.

It is difficult to state which error component is more impacted by WD error. The wrong directionality of polluted air masses likely affects the mean value (bias) as well the shape (variance) of the signal since it alters the source–receptor relationship (Vautard et al., 2012; Gilliam et al., 2015). WD error effects on the associativity structure of the modeled–observed time series is less clear however.

3.3 Chemical species: mean square error and error apportionment

3.3.1 CO

CO is a moderately long-lived primary pollutant principally produced by incomplete combustion of fossil fuels, wildfires and, on the global scale, by the oxidation of methane. CO also acts as precursor to ozone. Results of the AQMEII3 models for CO are reported in Figs. 9 and 10 and in Table S5.

In general, there are profound differences between the CO statistics for EU and NA, with the latter showing a more marked temporal and spatial dependency as well as model-to-model variability (the yearly mean observed values of CO in EU and NA are of 336 and of 248 ppb, respectively). The EU error (Fig. 9a) is, generally, uniform across models and
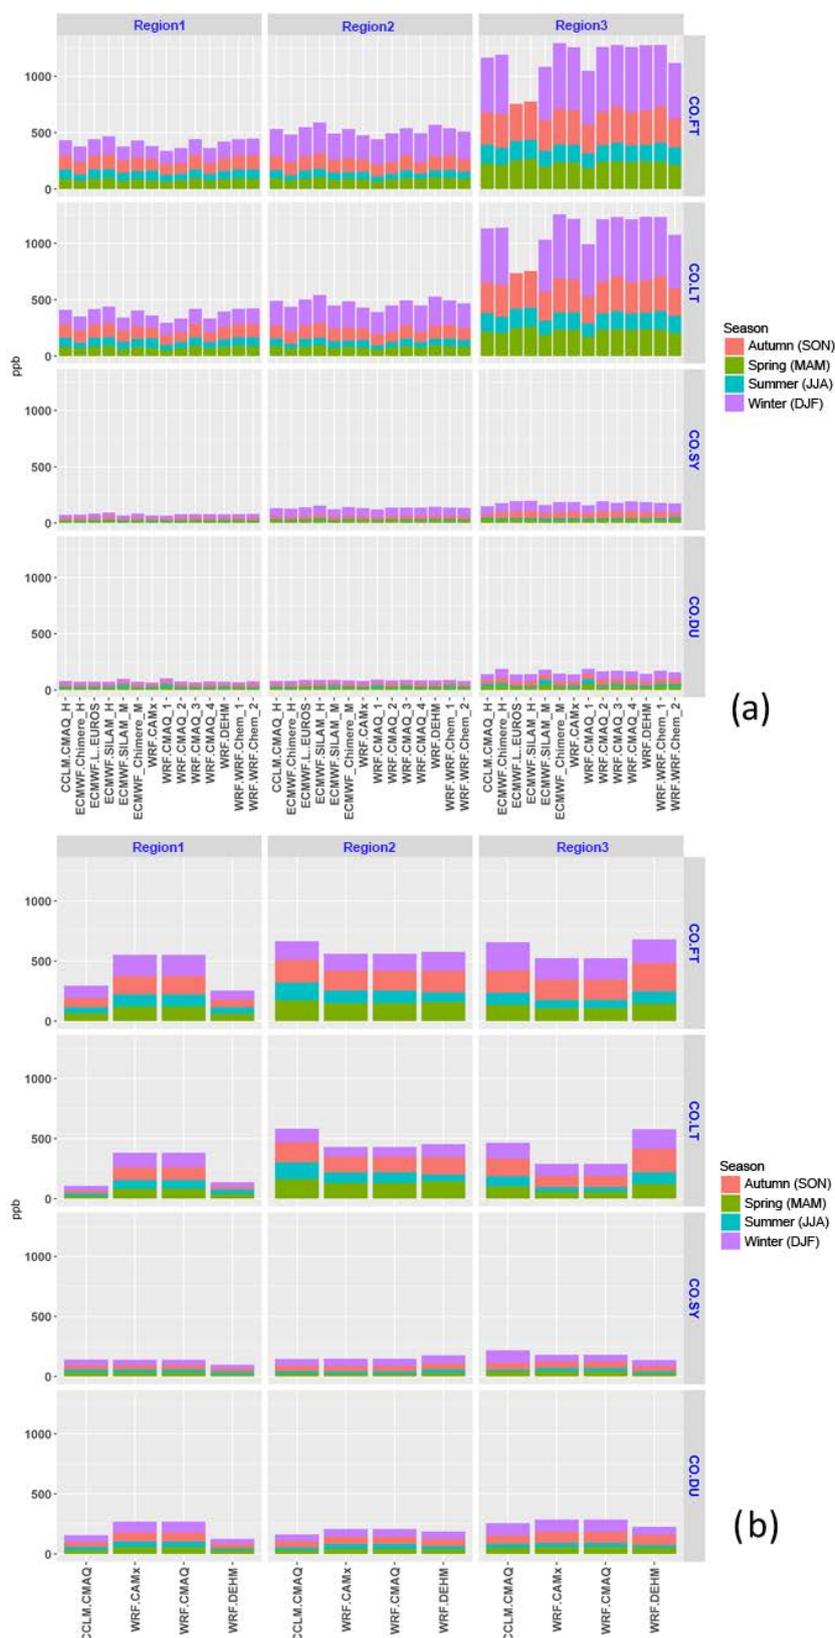

Figure 9. RMSE (ppb) for CO by spectral component and season (panel **a** for Europe and **b** for North America). FT is the full (unfiltered) time series, LT, SY, and DU are the long term, synoptic, and diurnal components, respectively.
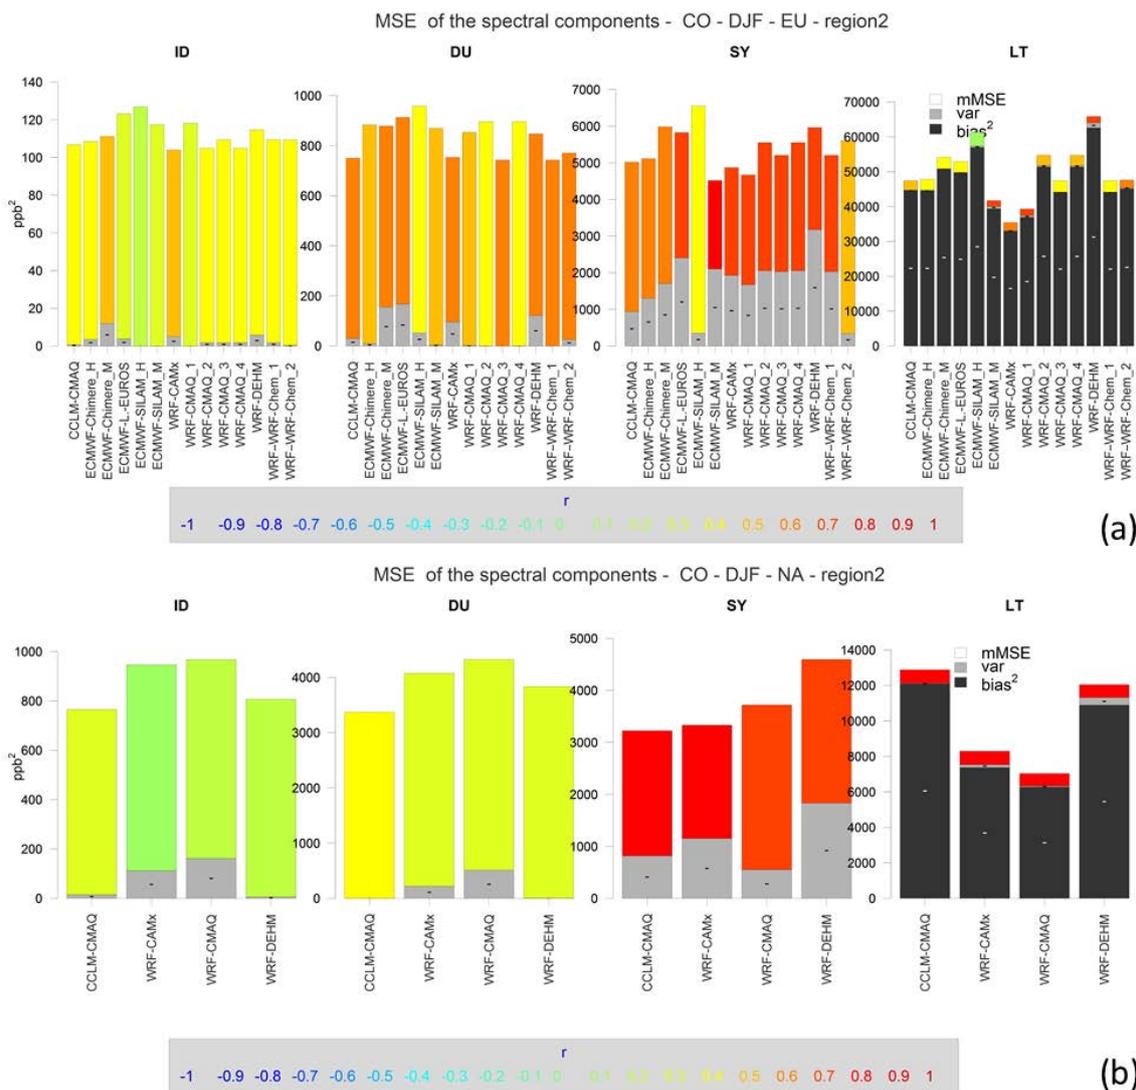

Figure 10. MSE (ppb^2) breakdown into bias squared, variance, and mMSE for the spectral components of the spatial average time series of CO during the months of December, January, and February (DJF) based on Eq. (6). The bias is entirely accounted for by the LT component. The signs within the bias and variance portion of the bars indicate model overestimation ($+$) or underestimation ($-$) of the bias and variance. The color of the mMSE share of the error is coded based on the values of r, the correlation coefficient, according to the color scale at the bottom of each plot. Top panel is EU; lower panel is NA. Similar plots for the other two subregions are reported in the Supplement.

subregions; it is approximately 3 times higher in winter than in summer. The magnitude of the SY and DU errors is comparable ($\sim$ 15–25 ppb on average in EU1 and EU2, sensibly higher in EU3). For NA (Fig. 9b) the DU and SY errors are also similar, but they vary by model, subregion, and season.

The homogeneity of error in EU suggests that it originates from a common source. Previous investigations (Innes et al., 2013; Giordano et al., 2015) indicate that the boundary conditions have a limited contribution to the bias of CO within the interior of the domain where the emissions are far more important. In particular, the MACC inventory used by the EU regional models likely underestimates the CO emissions (especially in winter; Giordano et al., 2015). We conclude that

the cause of model bias for CO is most probably attributable to the emissions and to a lesser extent the generally overestimated surface wind speed (Sect. 3.1.1). Sensitivity of the model error to emission changes for CO is discussed in the next section.

The correlation coefficient for EU generally peaks in spring (LT component), while it is at a minimum for the LT component in winter and is overall poor for the DU and SY components. In contrast, for NA the minimum correlation coefficient is observed in spring and summer (LT component), with the correlation for the DU component having a mixed behavior depending on the subregion, but it is typically low in summer (Table S5).

The winter LT error for EU is of ~ 140–220 ppb in EU1 and EU2 and up to 600 ppb in EU3, typically higher than in NA (~ 100 ppb, peaking in autumn and mostly due to model underestimation), while the opposite holds for the DU and ID error, which are significantly lower in EU (Fig. 10) than in NA (except for EU3). Since CO is a primary pollutant, its error is affected by the diurnal dynamics of the PBL height, which is most problematic in winter when modeled PBL has the tendency to become too stable too early, anticipating the evening transition (Pleim et al., 2016). In fact, the biases of CO and those of PM_{10} (another primary pollutant) in winter are highly correlated for almost all models (not shown), indicating a common cause of the error. The overestimation of WS discussed in Sect. 3.1 also contributes to further dilute the concentration of primary species such as CO (for example correlation (bias$_{CO}$, bias$_{WS}$) $= 0.60$ for the CMAQ4 model in EU2 during winter).

The error due to variance in EU (underestimated by the models) and mMSE are significant in the DU and SY components in winter (Fig. 10a). In particular, the variance error of winter DU is small compared to the mMSE, which accounts for almost the entire DU error, up to over 30 ppb. For SY, the model SILAM_H shows an mMSE error of over 75 ppb, the variance part being approximately null. On average, the DU and SY errors are approximately similar for all EU models (~ 45 for DU and ~ 65 ppb for SY), indicating some common error leading to poor associativity, which typically corresponds to lagged timing of the observed and modeled signals. An example of this might be the poor representation of the diurnal variation of the emissions (e.g., Makar et al., 2014). A further reason could stem from the lack of temperature-dependent emissions (the current emission inventory processing approach employs constant temporal emission profiles, and therefore cold–warm episodes are not incorporated in the modeled emissions even though these episodes do affect real-world emissions). The lack of temperature-dependant emissions is likely to have a strong effect for CO since about 50 % of CO emissions comes from residential heating (at least in middle and northern European countries). A test of this hypothesis is currently under investigation by running the CCLM-CMAQ model with a set of emissions using temperature data for the temporal disaggregation for residential heating emissions.

While the SY error is comparable for the two continents, the DU and ID errors are remarkably higher in NA (all subregions, also due to an excess of variance) and for several instances they are comparable or even higher than the LT error. With the exception of the WRF-DEHM model (variance error negligible), the DU and ID errors for the NA models are due to both mMSE and variance.

3.3.2 Sensitivity simulations with reduced emissions and boundary conditions

Additional sensitivity runs were carried out by the majority of modeling groups, in which the amount of anthropogenic emissions were reduced by 20 % in both the boundary conditions and the modeling domain. It is instructive to assess the error variation between the sensitivity runs (denoted as "s20 %") and the base case for primary species such as CO:

$$\%\mathrm{RMSE} = 100 \times \frac{\mathrm{RMSE}_{CO}^{s20\%} - \mathrm{RMSE}_{CO}^{base}}{\mathrm{RMSE}_{CO}^{base}}.$$

Figure 11 reports the error variation for central Europe (subregion EU2), where the effect of local CO outweighs the influence of the CO entering from the boundaries (similar plots for the other two EU subregions are reported in the Supplement). A decrease of 20 % CO produces a RMSE variation of ~ 10 % (averaged over models and components). A naïve projection indicates that a reduction of 100 % (thus removing CO from emissions and boundary conditions altogether) would produce a variation of the error of ~ 50 %. The sign of the error variation indicates that there are circumstances where a reduction of the base case emissions is actually beneficial since the error is reduced (even substantially in the instances where the emissions were overestimated in the base case).

The DU component for CO is the most sensitive to emission changes, with an average of ~ 24 % error variation in summer. The SILAM model is the most sensitive to changes in the amount of pollutants entering the domain. Striking error differences with respect to the base case are detected for summer CO (DU error improved by 50 %), possibly pointing to false peaks in the base case that contribute heavily to the RMSE (as suggested by the low correlation coefficient, Table S5). The reduction of the emission by 20 % lowers the peaks and could be the explanation for the improvement observed for the s20 % scenario for SILAM.

3.3.3 NO

NO is emitted by both natural and anthropogenic sources and its chemistry patterns are closely connected to those of NO_2 and ozone. Due to the fast ozone–NO titration reaction, the uncertainty in emissions, transport, and vertical mixing dominates the uncertainty in chemistry. Since no observational data were available for NA, the discussion is limited to EU. The European Environment Agency (EEA) reports an estimated uncertainty for NO_x emission of ~ 20 % (EEA, 2011); Vestreng et al. (2009) found ± 8–25 % uncertainties in EU NO_x emissions, in line with other similar bottom-up uncertainty studies (see Pouliot et al., 2015). A further source of uncertainty and model-to-model difference is the vertical emission profiles adopted and how these are interpolated to the vertical grids used by the models. Within the SILAM model, for example, the vehicular traffic emissions are re-
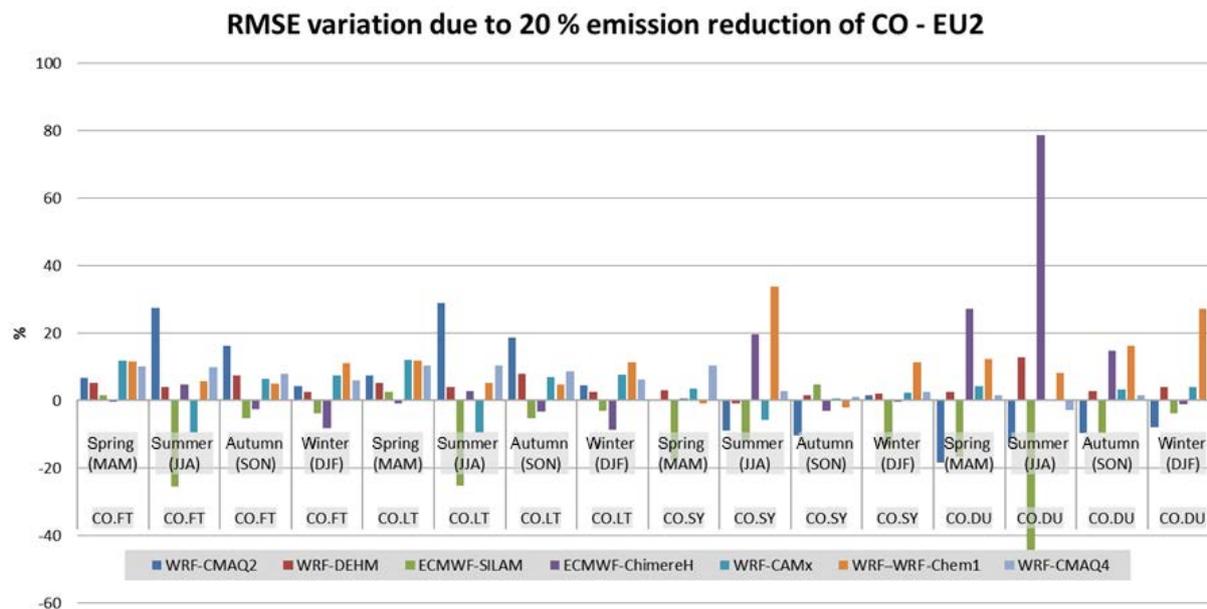

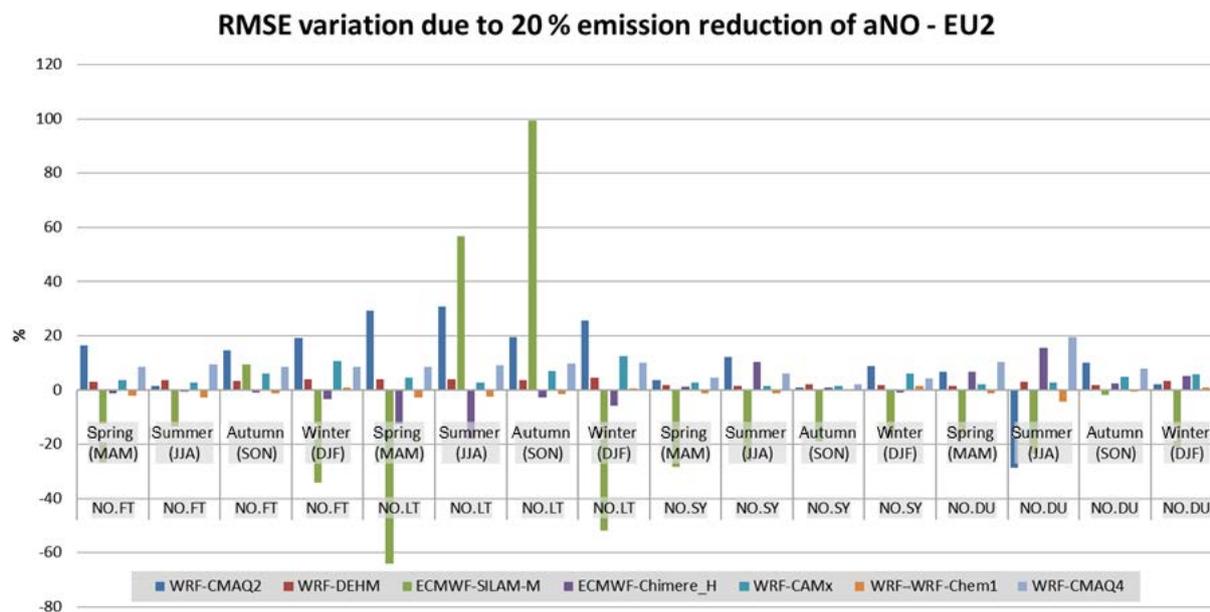

Figure 11. RMSE variation between the s20 % scenario (anthropogenic emission and boundary condition reduced by 20 %) and the base case for CO in EU2.

leased largely at the bottom of the first layer. This sub-grid information about the vertical location of the plume used in the vertical transport scheme further suppresses the mixing to the upper layers, thus keeping the surface concentrations higher.

The analysis of the RMSE for NO in Fig. 12a shows how the largest modeling error for NO occurs in winter and autumn, similar in magnitude for EU1 and EU2 ($\sim$ 7 ppb), while it is more than double in EU3 (up to 30 ppb). The DU and SY errors are comparable in magnitude (although the DU error is slightly higher) and are approximately evenly distributed among the models. For NO the error of the SY component is also model-independent, as noted for CO and as will be discussed for ozone and PM$_{10}$. Because it is mainly composed of mMSE error (Fig. 12b), it can be hypothesized that the unexplained meteorological variance is responsible for the majority of the SY error.

The winter bias and variance errors are predominantly negative, indicating model underestimation and reduced variability. The opposite holds for the two instances of SILAM, for which the bias and variance are positive (all subregions). This can be associated with the underestimated ozone concentrations in this model. The applied vertical emission profiles mentioned earlier for this model could also have an influence. The correlation coefficient varies greatly by model, by components, and by season, and it typically degrades for the summer seasons (LT component, most models). The SY component also exhibits low values of r, especially in summer for EU1 and autumn (Table S6). The large variability of the correlation coefficient indicates that the models are not

able to capture the fluctuations of this important precursor at all scales.

From the error decomposition plots (Fig. 12b) it emerges that

– the LT components show a mMSE error approximately uniform for all modeling systems (between $\sim$ 3 and 4 ppb);

– in the majority of cases the mMSE error dominates the ID, DU, and SY components; and

– the SY component has an error comparable to that of DU for the mMSE part, but it is overall higher due to a predominant lack of variance (as high as 50 % of the total SY error for some models).

Due to its fast chemistry and short traveling distance, the error of representativity for NO (mismatch of the area of representativeness between models with grid spacing of $\sim$ 15 up to 50 km and point measurements) is likely more significant than for other pollutants with a longer lifetime. NO is almost a primary pollutant with negligible deposition (Wesely and Hicks, 2000) and small influence of the boundary conditions (Giordano et al., 2015); therefore, observational sites are affected by local-scale effects in the range of a few kilometers, below the grid spacing of the majority of the models. This has the effect of higher observed mean values compared to the models (enhancing the bias error) and stronger variability in the observations than the models (variance error).

The correlation between the bias of NO and the bias of the other species reveals strong links at several temporal scales
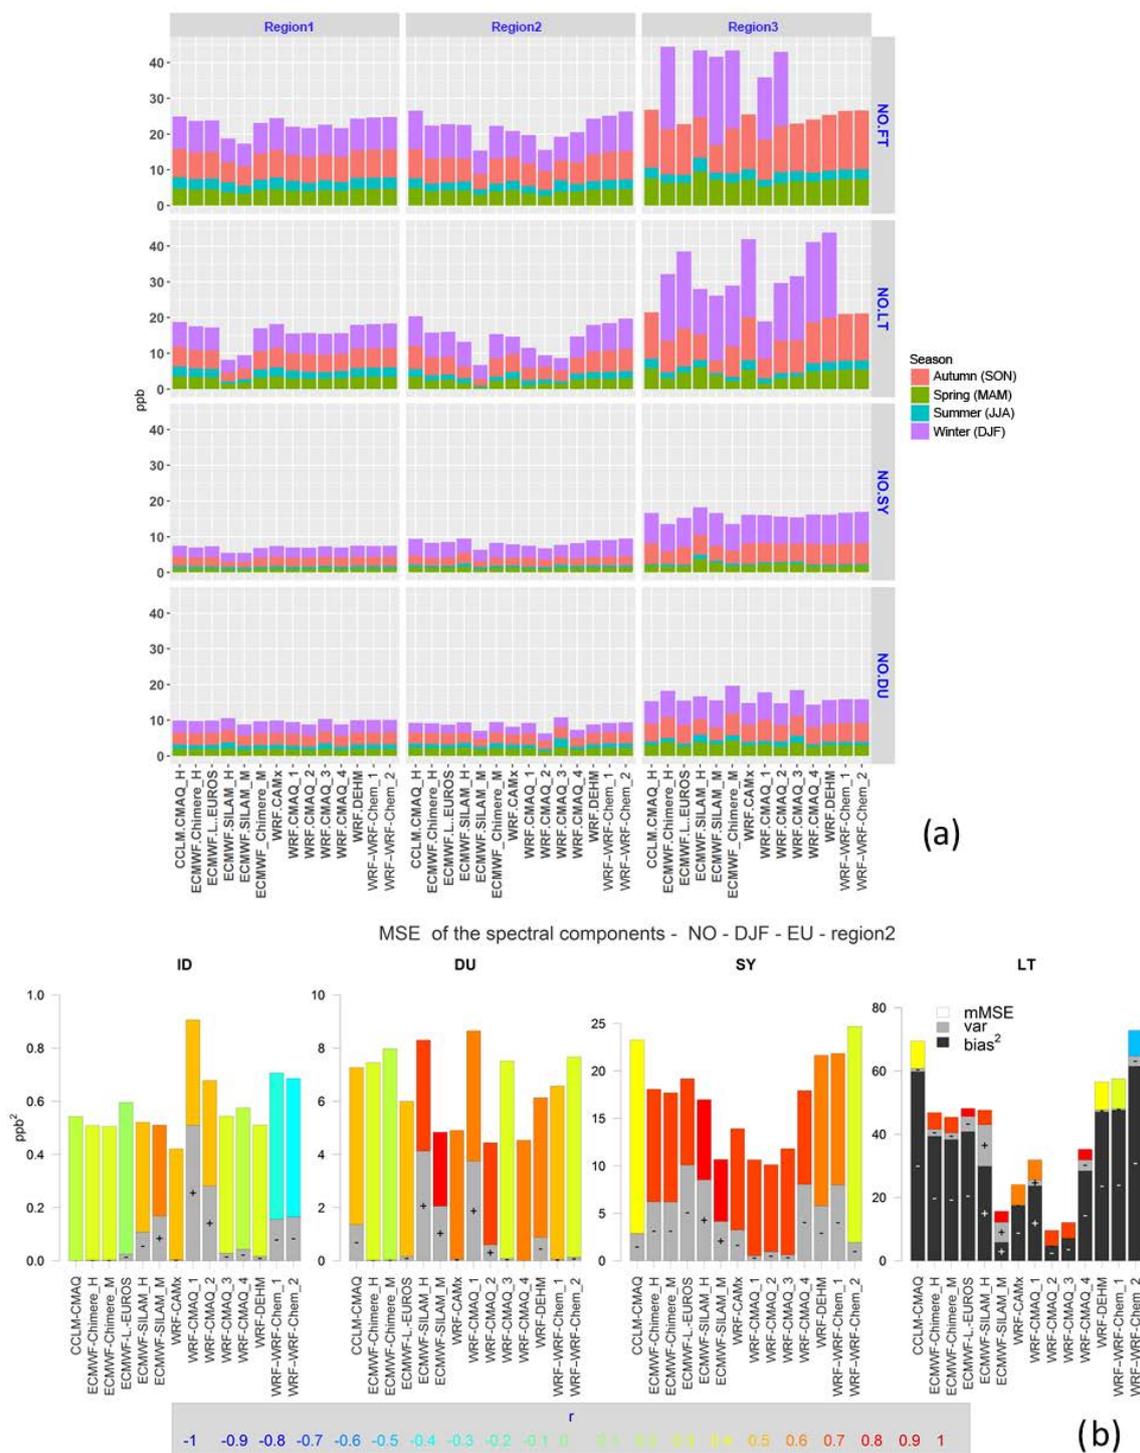

Figure 12. Top panel is as in Fig. 9 but for NO (EU only). Lower panel is as in Fig. 10 but for NO (EU only).

(less for the DU timescale though) and also in terms of processes, although it varies greatly by model. For instance, corr (bias$_{NO}$, bias$_{O_3}$) is overall strong (and negative) for the majority of the models but for different timescales, i.e., stronger for the SY components for some models (e.g., LOTOS-

EUROS), or for LT (SILAM), or for DU (CHIMERE). Additional analyses are envisioned to determine the causes of such behavior.

Figure 13. RMSE variation between the s20 % scenario (anthropogenic emission and boundary condition reduced by 20 %) and the base case for anthropogenic NO (aNO) in EU2.

3.3.4 Sensitivity simulations with reduced emission and boundary conditions

The analysis discussed in Sect. 3.3.2 is repeated here for NO and results are presented in Fig. 13. A decrease by 20 % of the amount of NO in the domain produces a variation of RMSE of ∼ 8 % (averaged over models and spectral components). A naïve projection indicates that a reduction of 100 % (thus removing the production of NO from emissions and boundary conditions) would produce a variation of the error of ∼ 35 %. Such an amount is less than that found for CO (∼ 50 %, Sect. 3.3.2), which is consistent with the photochemical processes involving NO but not CO.

The LT component is the most sensitive to changes for NO, with an average of ∼ 17 % error variation (and up to 20 % in autumn, both positive and negative). Again, the SILAM model is the most sensitive to changes in the amount of pollutants entering the domain. Remarkable differences between the s20 % scenario and the base case are detected for summer and autumn (LT error variation of 100 %; Fig. 13). The improvement of the error of SILAM (and of the other models) for the s20 % scenario is due to the overestimation of NO mean concentration in the base case (positive bias, Table S6).

3.3.5 NO$_2$

Primary NO$_2$ is emitted by a variety of combustion sources and plays a major role in atmospheric reactions that produce ground-level ozone. NO$_2$ is also a precursor to nitrates, which contribute to PM formation. As for NO, only a small portion of the total error is expected to stem from the boundary conditions. The AQMEII3 modeling systems attribute a

fraction of NO$_2$ emission ranging between 3 and 10 % of the total NO$_x$ emissions (some models treat the NO$_2$ emissions from the transport sector differently; see Table 1). The results of the error analysis discussed hereafter do not reveal grouping of model behavior consistent with the choice of the NO$_2$-to-NO$_x$ emission ratio though, considering the fast chemistry between NO and NO$_2$.

The RMSE distribution (Fig. 14a, b) shows a marked model-to-model variability in the LT and DU components, while it is more uniform for the SY component, also in the seasonal stratification. Moreover, the error distribution is shown to be weakly dependant on the specific subregion (for both continents, especially for the DU component), suggesting that regional features (e.g., differences in climate between the regions) have little impact on NO$_2$ performance, which is mostly affected by chemistry and error in the meteorology. Local-scale features (e.g., representation of urban–rural emission differences) may still be important, but they may have similar errors in all regions.

The largest error occurs in winter (both continents) and is shared approximately equally between the SY and DU components (for some models the SY and LT errors are comparable due to the small bias).

The bias is the main contributor to the NO$_2$ error and stems from a model underprediction of the mean observed concentration during the entire year (but, with the exception of the winter season, it is positive for WRF-CMAQ in NA and WRF-CMAQ1 in EU; Table S7). The bias is probably caused by a combination of factors, including emission estimates (e.g., underestimation of residential combustion), PBL height and vertical mixing at night (when wood com-
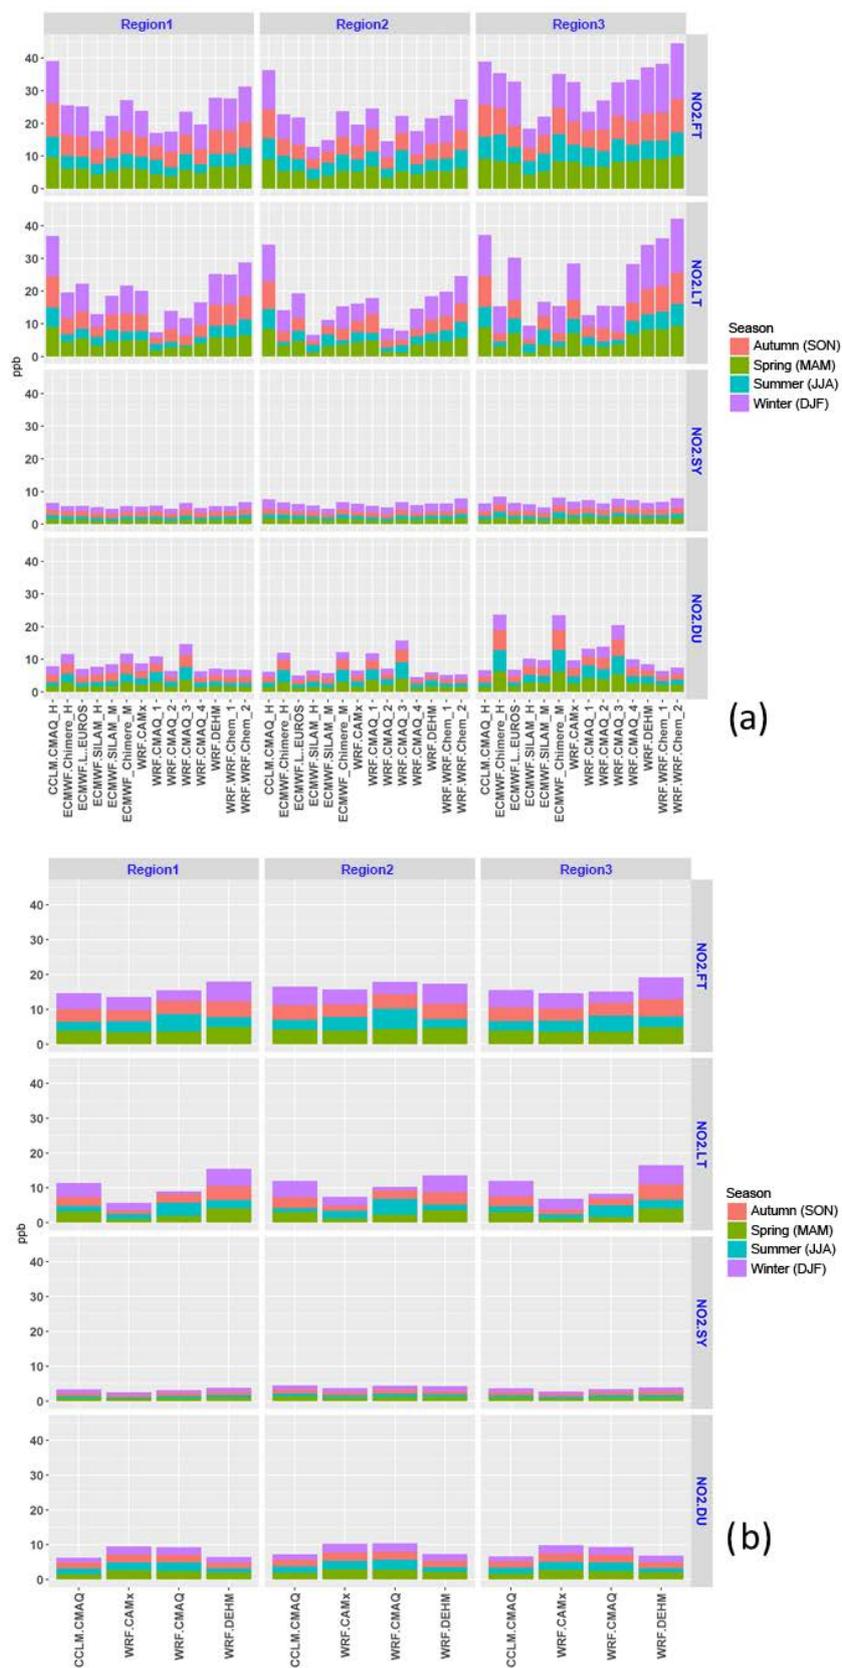

Figure 14. As in Fig. 9 but for NO$_2$.

bustion emissions tend to be maximum; e.g., Denier van der Gon et al., 2015), and missing processes acting as systematic errors, such as shading effects of forested canopies (e.g., Makar et al., 2016). However, the tendency of NO_2 measurements to be overestimated by the majority of commercially available instruments for detecting NO_x (Steinbacher et al., 2007) needs to be taken into account. The magnitude of the bias is higher in EU (from ~ 1.3 pbb of WRF-CMAQ1 in EU1 to ~ -12.5 ppb of CCLM-CMAQ in EU3) than in NA (the maximum being ~ 5.5 ppb in NA3 by the WRF-DEHM model), with the mean observed values being 11.5 and 10.5 ppb for EU and NA, respectively.

The correlation coefficient is typically higher in spring–autumn and poorer in summer–winter (in summer there are several instances of negative correlation; Table S7). The LT component for EU and the LT and SY components for NA are those with higher correlation coefficients, while SY and DU are the poorest in EU and DU is the poorest in NA (but still higher than ~ 0.4).

The median value of the modeled accumulated deposition per unit area (Fig. S11 in the Supplement) for NO_2 ranges from ~ 0.4 to ~ 1.9 kg km^{-2} for EU (nine models) and from ~ 0.3 to 2.3 kg km^{-2} for NA (two models). With the exception of the WRF-DEHM model (similar values for EU and NA of 0.3–0.4 kg km^{-2}), the modeled values for NO_2 deposition are uniform across the EU models, while the deviation between the two NA models for deposition is not negligible, also considering the different native grid sizes of 50 and 12 km (WRF-DEHM and WRF-CMAQ, respectively). Therefore, for the majority of the EU models, model-to-model differences in the error are unlikely due to significant difference in the deposition, while differences remain a possibility for NA.

The magnitude of the error for NO_2 resembles that of NO and ozone, although the apportionment reveals significant differences. In fact, while NO includes variance error and a uniform share of mMSE, the LT error of NO_2 for winter is almost completely determined by the bias, for both continents (Figs. 15 and 16). The other NO_2 spectral components (ID, DU, SY) reveal more profound differences with respect to NO, both in terms of bias and of error apportionment. The ID error for NO_2 is even smaller than that of NO (less than 1 ppb) and can be regarded as noise. The DU (~ 1.5 ppb) and SY (~ 1 ppb) errors are also considerably smaller than for NO (both continents), although the DU error presents some excess of variance for WRF-CMAQ3 and the two instances of the CHIMERE model (Fig. 15).

The model-to-model variability of RMSE for the LT component Fig. 15) is very similar to that of NO (Fig. 12), while the DU variability resembles that of ozone (Fig. 18), although for NO_2 the DU error is lower in magnitude and more uniform across seasons.

Moreover, NO_x observations are strongly affected by local emissions and thus the error may stem from the incommensurability of comparing grid-averaged values with point measurements highly affected by local-scale emissions. However, the error apportionment analysis carried out separately for rural and urban background stations (the area type classification is taken for the stations metadata) does not reveal any relevant differences (Fig. 15 for EU2 and Fig. 16 for NA1), if not a slight increase in the variance error over both continents, thus likely excluding chemistry-related model errors.

3.3.6 Ozone

Due to the adverse effects on human health and to the impact on climate, tropospheric ozone is regulated in EU and NA and substantial efforts are made to improve model predictive skill for this pollutant. Tropospheric ozone can be either transported from regions outside the modeled domain, be the result of stratosphere–troposphere exchange, or be produced locally by photochemistry through oxidation of VOCs and CO in the presence of NO_x and sunlight. Due to its photochemical nature, ozone production is directly influenced by temperature through speeding up the rates of the chemical reactions and increasing the emissions of VOCs (e.g., isoprene) from vegetation (Jacob and Winner, 2009). Along with dry deposition, chemistry can act as a local sink to ozone depending on the photochemical regime.

Results of the AQMEII3 modes for ozone are reported in Figs. 17 and 18 and in Table S4. Overall, the correlation between modeled and observed ozone time series is higher for winter and fall than spring and summer in EU, while the opposite holds true in NA where the maximum correlation is observed in summer (all subregions; Table S4). In EU, the RMSE is generally lower in winter than in the warm seasons (summer and spring; RMSE in summer ranges between 4.3 ppb of WRF-Chem1 in EU1 and 21 ppb of WRF-CAMQ1 in EU3), with the exception of the CCLM-CMAQ model for which the RMSE peaks in autumn (all subregions).

Due to the strong and well-defined diurnal cycle characterized by ozone formation and loss, the correlation coefficient is generally higher for the DU component, while it tends to be lowest for the SY component (Table S4 and Fig. 18). The SY component often exhibits the lowest correlation among all components, especially in summer (EU) and spring (NA), possibly due to the combined effect of transport of precursors, deposition and chemistry (formation–depletion of ozone from precursor emissions in the regions where the ozone is transported; Bowdalo et al., 2016). However, the SY error is generally small (~ 2–3 ppb, although higher for EU3, where the SY error is double that of the other subregions) and is mostly due to mMSE. It is thus characterized by poor coefficients of determination and underestimated variability (Eq. 6). Therefore, the SY component suffers from low precision (for some models $r < 0.3$), meaning that the variability of the synoptic mechanisms needs further attention, especially in the meteorological conditions leading to high ozone level episodes and in relation to temperature, cloudiness, and radiation. The WRF-Chem2 model (with the highest error for
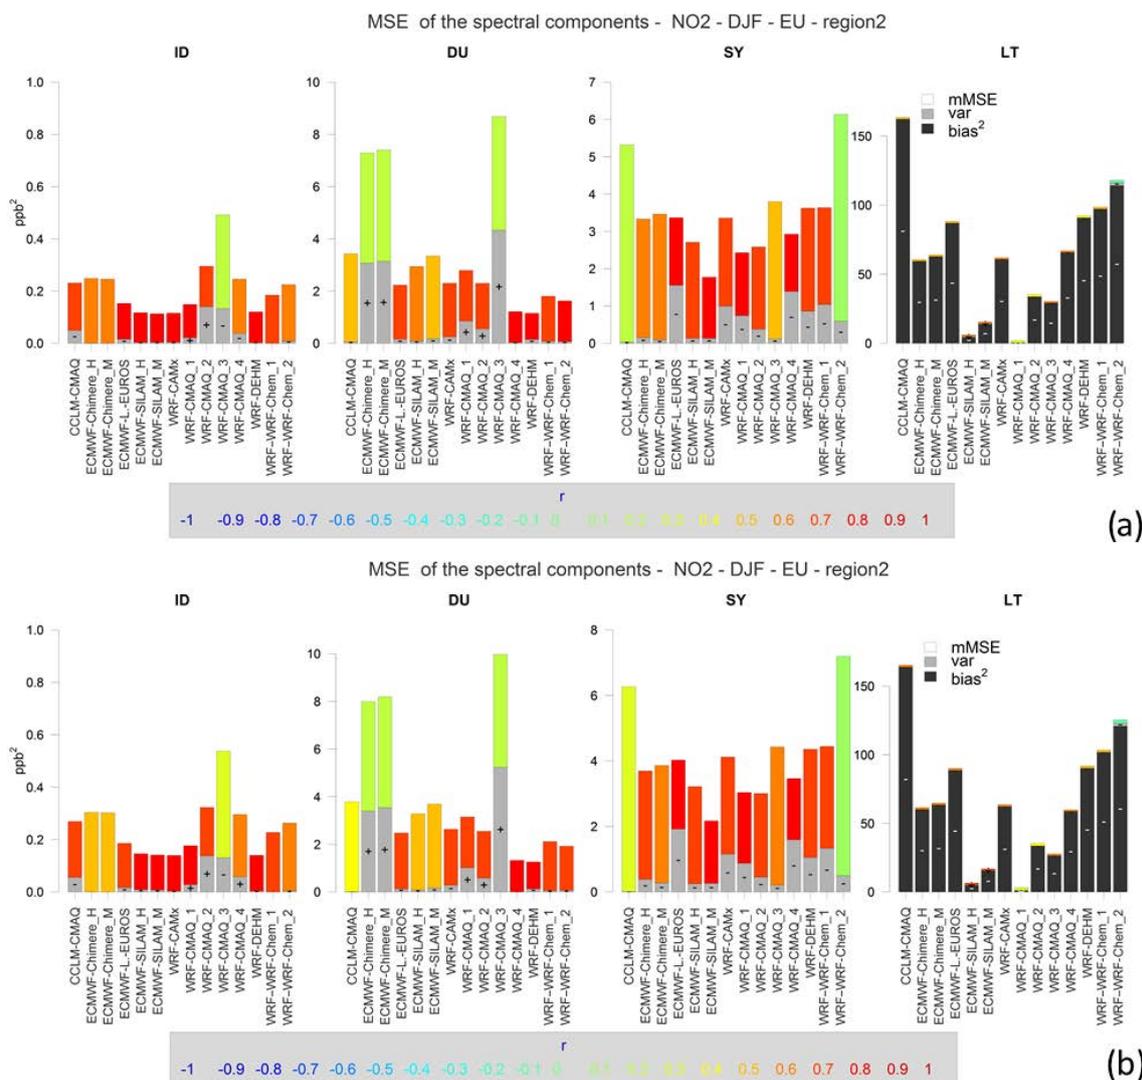

Figure 15. As in Fig. 10 but for NO_2 in EU2. Upper panel is urban sites only (223 stations); lower panel is rural sites only (159 stations).

temperature, Fig. 2b) reports the largest SY error for ozone (especially the variance part). For this model, the correlation between the ozone and the temperature error for the SY component corr (err_{O_3}, err_{Temp})$_{SY}$ is 0.44 for the summer months in EU2 (not shown), which is among the highest; this helps to explain part of the SY error for ozone. Further possible causes could be associated with tropopause folding events, especially downwind of mountain areas (e.g., Bonasoni et al., 2000; Makar et al., 2010), which would also be in line with the larger synoptic error of ozone in EU3 (Fig. S4b), comparable for all models in the range of 3–4 ppb. In order to better characterize the mMSE part of the error for the periodic components, such as DU and SY, analyses of the phase and amplitude are ongoing.

The error of the DU component is largely due to the mMSE term (Fig. 18a), which is comparable for all models in the range of 2–5 ppb, with some significant excess

of variance for WRF-CMAQ2 and WRF-CMAQ3 in EU2 (~ 5 ppb). Some possible reasons are the dynamics of the nocturnal PBL and the timing of the ozone cycle, with an either too-fast or too-slow modeled ozone peak (e.g., Pirovano et al., 2012). Limitations of the models to reproduce the amplitude and phase of the daily ozone cycle were already highlighted in the first and second phase of AQMEII, mostly related to the representation of nighttime and stable conditions. Furthermore, the variance error for WRF-CMAQ2 and WRF-CMAQ3 can be induced by the bias of temperature and/or concentration of ozone precursors. For WRF-CMAQ2 (WRF-CMAQ3), corr (err_{O_3}, err_{Temp})$_{DU}$ is 0.88 (0.94) and corr (err_{O_3}, err_{NO_2})$_{DU}$ is 0.86 (0.83, summer months, EU2; not shown), which indicates that the errors of the temperature and NO_2 fields are strongly associated with the error of ozone at the DU scale. PBL representation during transitions is a long-standing issue of AQ models.
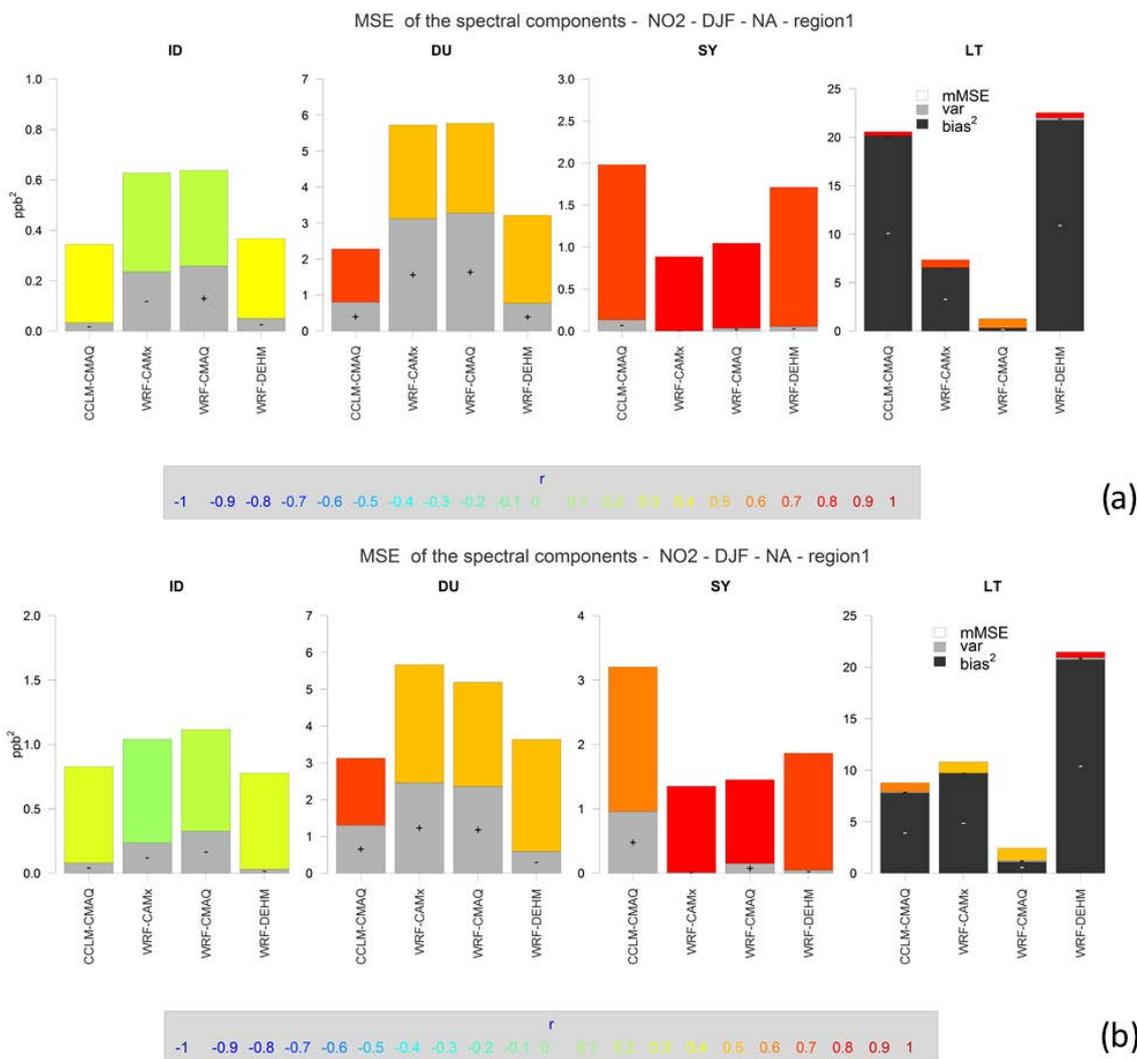

Figure 16. As in Fig. 10 but for NO_2 in NA1. Upper panel is urban sites only (39 stations); lower panel is rural sites only (10 stations).

The error in the LT component is dominated by the bias error (almost completely for NA; Fig. 18), although with significant exceptions in EU (for CCLM-CMAQ the mMSE error of the LT component is larger than the bias portion). The May–September ozone LT bias for EU2 peaks at 12–13 ppb (WRF-CMAQ1), while it is ~ 6 ppb in NA3 (but in excess of 20 ppb in NA2 by the WRF-DEHM model; the yearly average measured ozone mixing ratio is 26.5 and 29 ppb for EU and NA, respectively). The bias of the precursors and of the meteorological fields is typically highly correlated with the bias of ozone. For instance, in EU2 for the WRF-CMAQ1 model, corr ($bias_{O_3}$, $bias_{Temp}$) is 0.65 and corr ($bias_{O_3}$, $bias_{WS}$) is 0.81 (summer months). The almost null NO_2 bias for CMAQ1 (among the lowest) combined with the positive bias for NO suggests that chemistry also affects the ozone bias of CMAQ1. Furthermore, the excess of ozone intrusion for the troposphere (discussed next) may

also factor in determining the high positive bias at the surface for this model.

According to Bowdalo et al. (2016), the bias of the ozone amplitude cycle linearly evolves with NO_x emissions, suggesting that correction of the error for ozone needs to start from NO_x emissions. Otero et al. (2016) showed that meteorological drivers account for most of the explained variance in ozone, especially over central and northwestern Europe. One of the main drivers of ozone is the daily maximum temperature in relation to the effect of temperature on emissions of VOCs. Therefore, while part of the bias error is possibly due to NO_x emissions, the mMSE and variance error are also likely induced by error in meteorology. Other documented biases are transcontinental transport in winter (Hogrefe et al., 2011) and missing processes during spring and summer, such as the large-scale effect of the absence of forest shading in the models (Makar et al., 2016), a too-rapid production of ozone from available precursors, and an underestimation of ozone
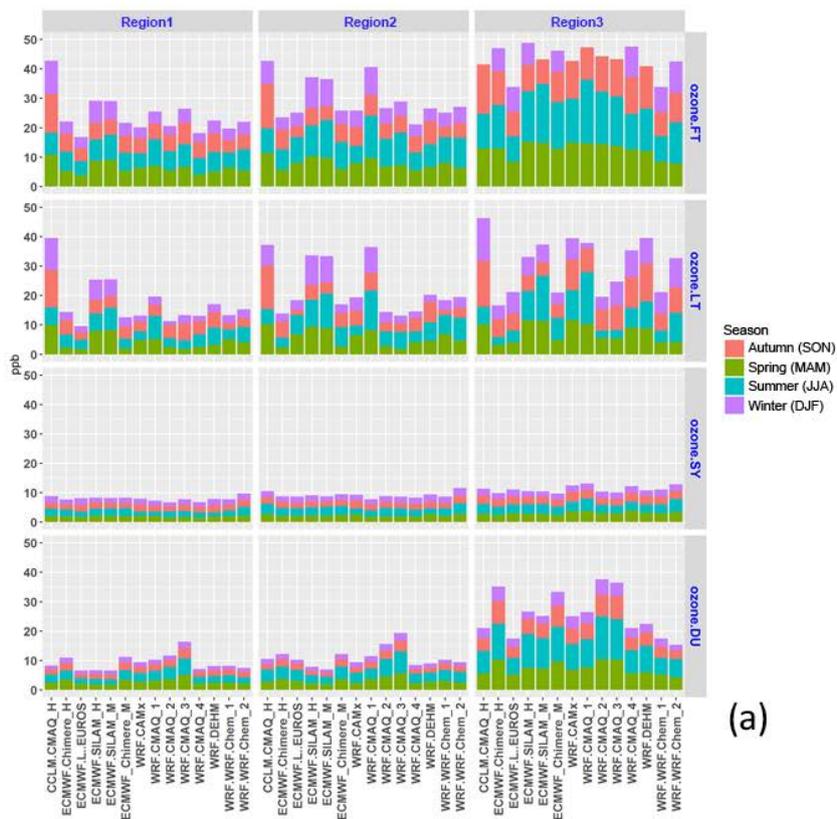

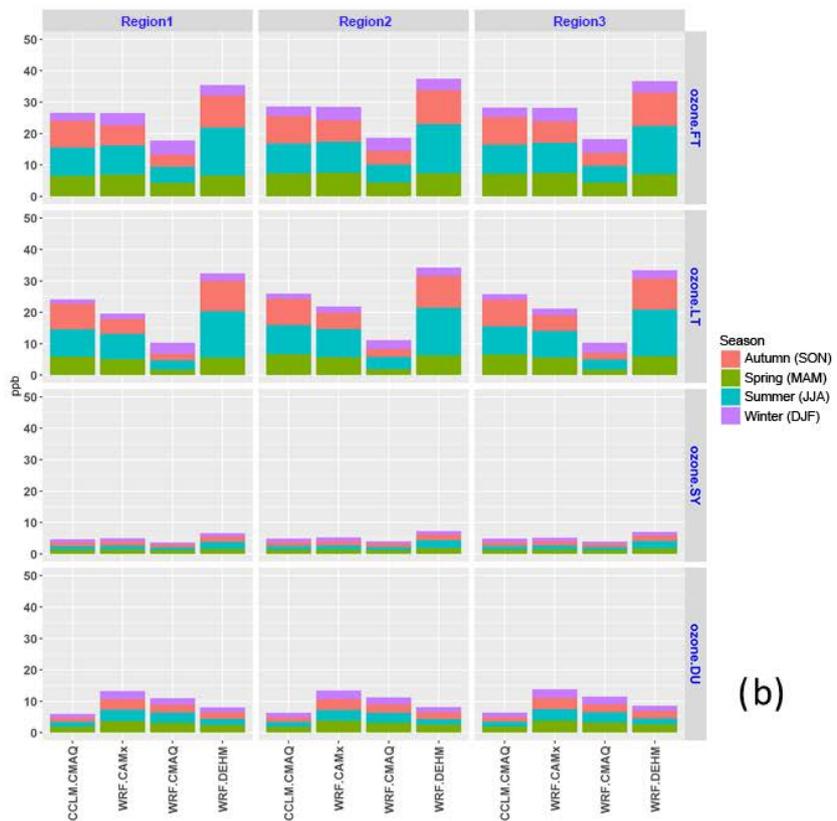

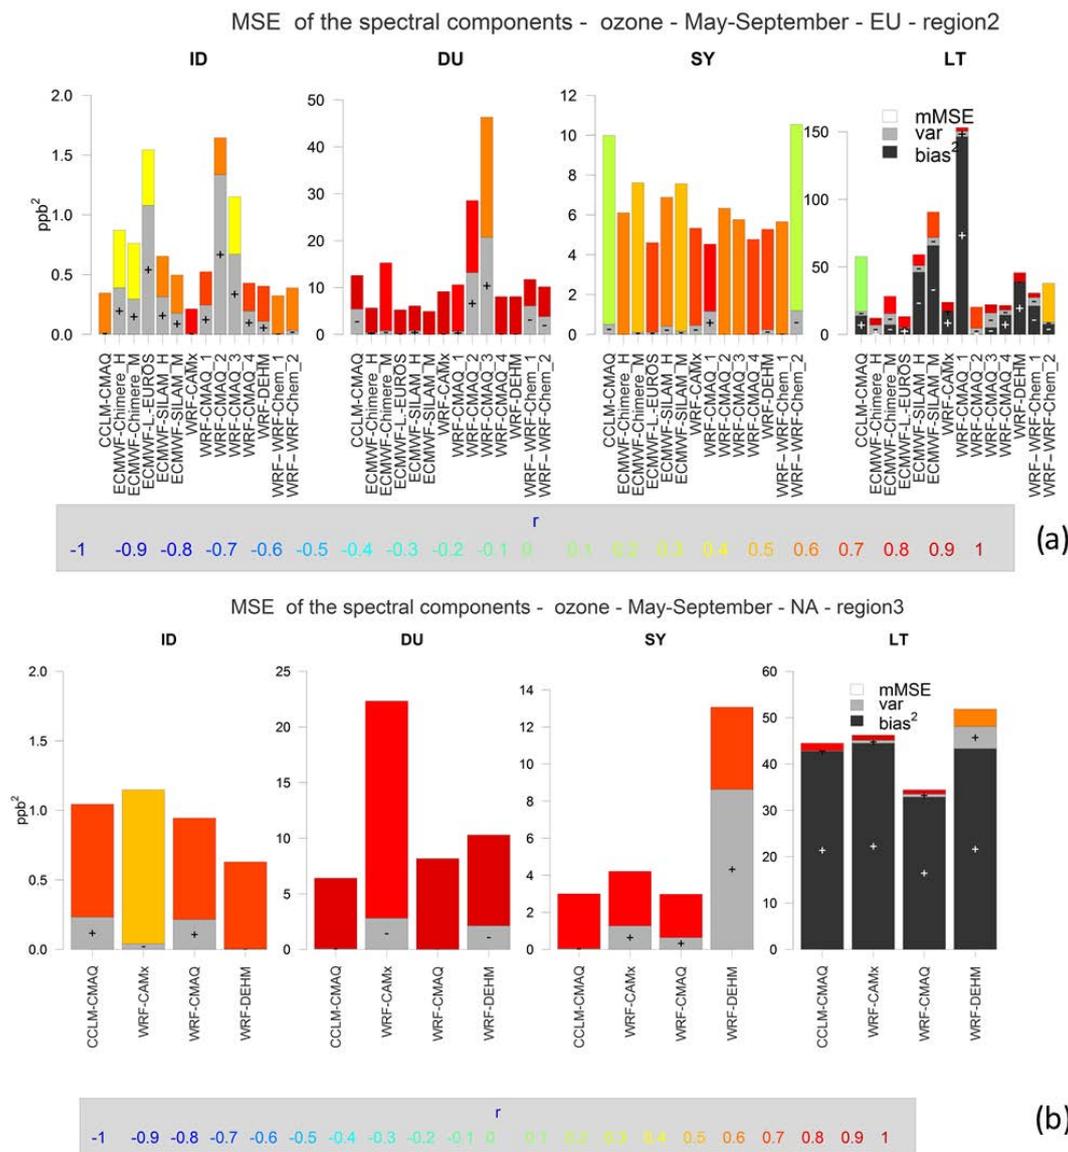

Figure 17. As in Fig. 9 but for ozone.

Figure 18. As in Fig. 10 but for ozone during the months from May to September.

deposition (Herwehe et al., 2011). Im et al. (2015b) also indicated a range of factors determining the difference in performance among models, such as the chemical mechanism, biogenic module, and VOC preprocessing, and the difference in microphysics affecting the photolysis, temperature, and radiation that act on the production of ozone.

Although the concentration peaks are associated with the ID and DU components, the contribution to the total error of the ID component is small (< 2 ppb) due to flattening of the spikes operated by the spatial averaging carried out prior to spectral decomposition. The noise of the ID component is reflected by the correlation coefficient being lower than the correlation of the DU component.

3.3.7 Ozone vertical profiles

Several studies have demonstrated the importance of extending the evaluation of air quality models to the troposphere (e.g., Solazzo et al., 2013; Makar et al., 2010; Herwehe et al., 2011), not only because of the vertical turbulent transport but also for the key role played by coupling of the PBL and the free troposphere in determining the ozone intrusion to the surface. In this section profiles of modeled ozone are compared with ozonesonde measurements.

A summary of the records provided by the ozonesondes for ozone are reported in Table 4. Plots of the simulated and observed ozone levels at fixed heights (through the EN-SEMBLE system, models and measurements are paired at the heights of 0, 100, 250, 500, 750, 1000, 2000, 3000,
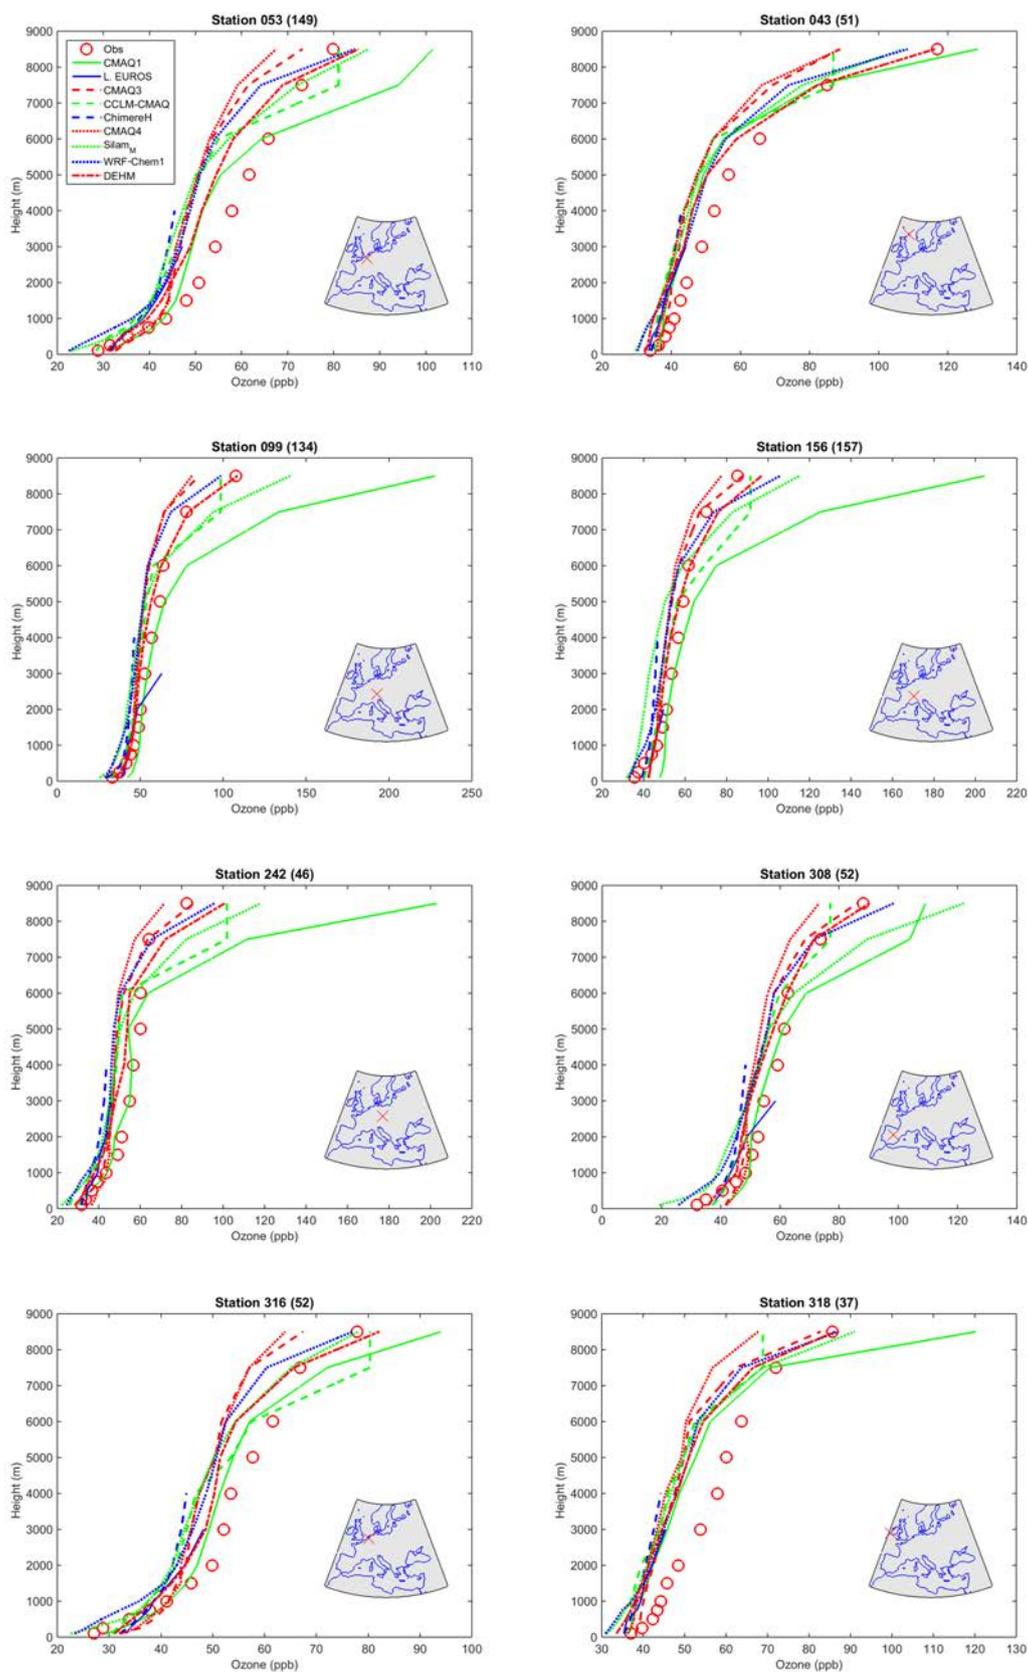

Figure 19. Ozone mixing-ratio profiles measured by ozonesondes launched from the European location indicated in the inset map (lower-right corner) of each panel. The profiles are time averaged over the number of hourly records reported in parentheses at the top of each panel. Legend as in the first panel.
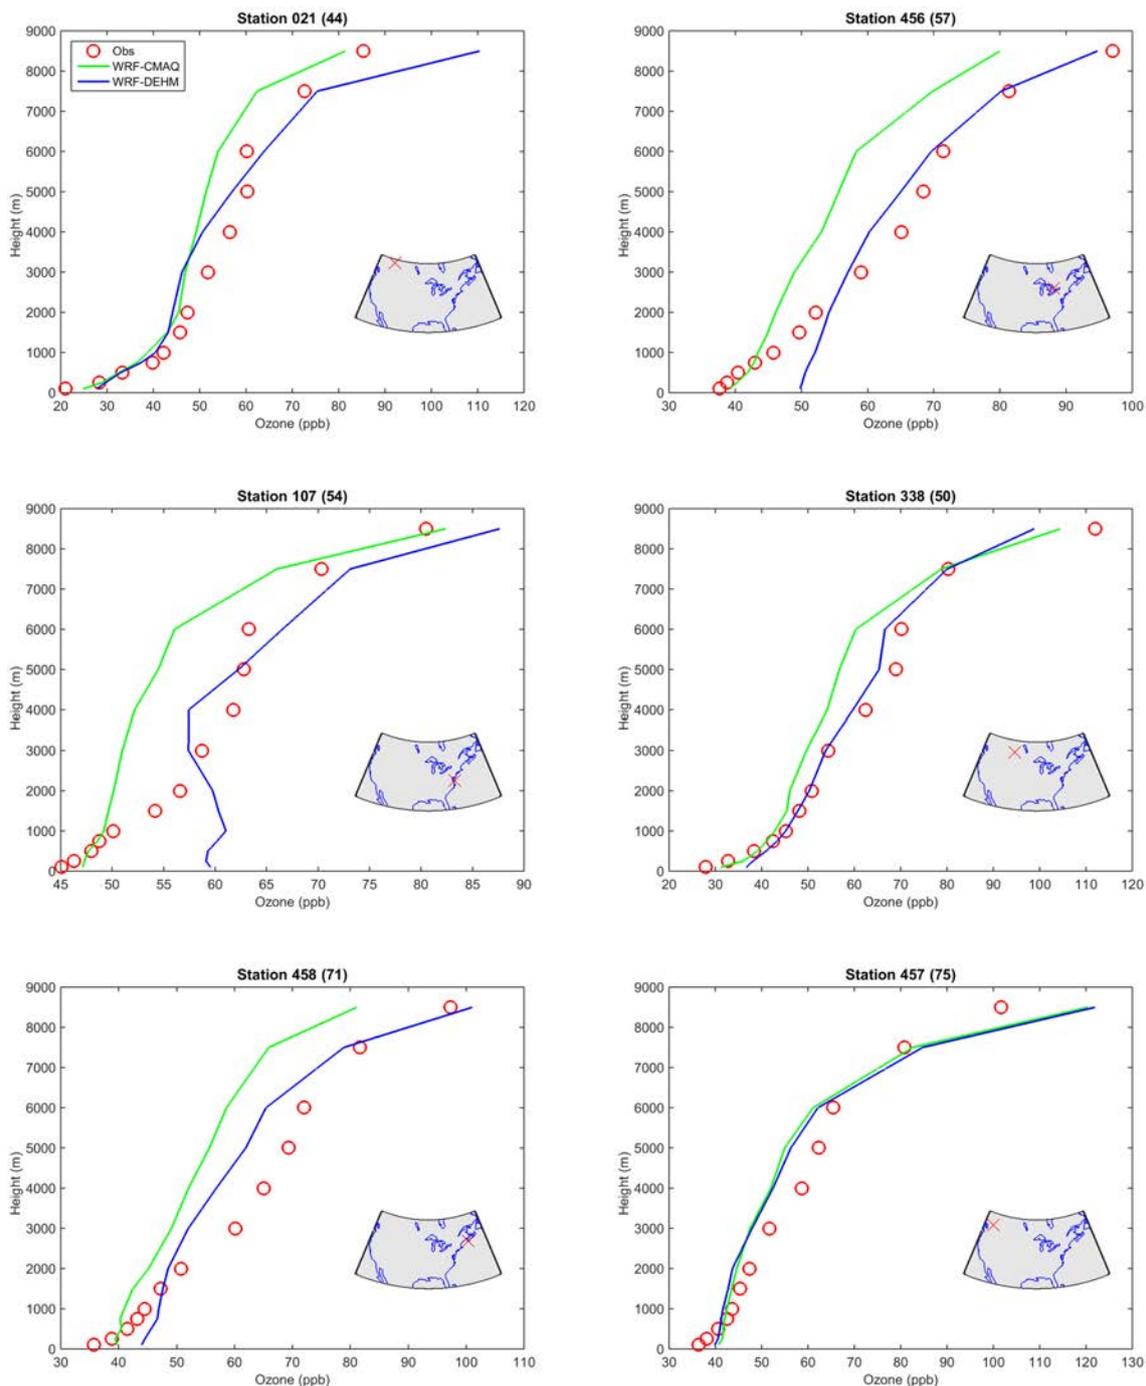

Figure 20. As in Fig. 19 but for North America.

4000, 5000, and 6000 m) are reported in Figs. 19 and 20. The ozonesonde data are mainly available during daylight, although two stations with nighttime data are available for NA (Table 4).

Overall, the general tendency of the models in both continents is to underestimate the ozone levels above the PBL, suggesting that not enough ozone enters the continental do-

mains through the inflow boundaries. The most significant underestimation (~ 10 ppb) is observed at the two stations closer to the western boundary for the EU (stations 318 and 043). The boundary layer deficit of ozone is a long-standing issue, seeing as similar conclusions were derived for the first (Solazzo et al., 2013) and second (Im et al., 2015b; Giordano et al., 2015) phases of AQMEII, as well as for other

studies (Katragkou et al., 2015), emphasizing the strong dependence of regional models on the lateral boundary, whose effects propagate far into the interior of the domain.

Towards the interior of the EU domain (stations 134, 157, 242) the profiles are in closer agreement with the observations, with the WRF-CMAQ1 model performing the best throughout the troposphere, possibly due to the overestimation of the entrainment of upper tropospheric ozone, as revealed by the strong gradient of WRF-CMAQ1 at 6000 m (Fig. 19). With respect to the other models (and SILAM in particular), the CMAQ runs show larger ozone availability in the residual layer above the PBL, which acts as a reservoir of ozone that becomes depleted the next day, increasing the concentration at the surface. It is possible that the PBL and vertical mixing within these models is too weak (Appel et al., 2016). Further analyses restricted to specific season and time of the day are required to validate this hypothesis.

For NA (Fig. 20), the general tendency is of slight-to-consistent (stations 71 and 75) overestimation within the PBL, underestimation for the WRF-CMAQ model, overestimation (stations 107, 456, and 458 – afternoon–night launches) at the surface, and mild underestimation above the PBL for the WRF-DEHM model.

3.3.8 Relationship between the bias of ozone, NO_x and Temperature

The relationship between the bias of NO and the bias of ozone is reported in Fig. 21 for the EU2 region (similar plots including the bias of NO_2 for EU and NA are provided in the Supplement). A linear relationship between the biases of the two species is detectable, which is more evident in winter. Large positive ozone bias is driven by underestimation of NO (a primary species), whereas the largest negative ozone bias corresponds to the largest overestimation of NO. The role of the temperature bias is less clear, but the NO_2 and ozone relationship (Fig. S7) suggests that large NO_2 bias is associated with temperature underprediction. The partition of NO_x emission into primary NO and NO_2 seems to suggest that the models adopting a 95 / 5 % ratio suffer lower ozone bias (at least in winter), although in general the clustering of models based on the NO / NO_2 share of total NO_x emission is far from robust. A simple linear regression between NO bias and ozone bias (based on the yearly time series) among the EU models suggests that the NO_x and temperature biases can explain, on average, ~ 35 and ~ 16 % of the variability of the ozone bias, respectively.

3.3.9 SO_2

SO_2 is another primary regulated pollutant, which in EU and NA, is mainly emitted from coal power plants and also from the residential heating and waste disposal sector. SO_2 acts as a precursor to sulfates, which are one of the main components of PM in the atmosphere. Any error in SO_2 is

likely inherited by these secondary species. The majority of models employed the prescribed vertical distribution by EMEP (Vestreng and Støren, 2000), while CMAQ4 in EU and WRF-CMAQ in NA adopted the Briggs plume rise algorithm (Briggs, 1971, 1972) accounting for the effects of modeled meteorology. SILAM, CHIMERE, and CCLM-CMAQ adopted the sector-dependent vertical emission profiles as in Bieser et al. (2011b). The EEA reports an estimated uncertainty for SO_2 emission of ~ 10 % (EEA, 2011); therefore, SO_2 emissions are expected to be more accurate than NO_x emissions. This is reflected in the low bias in both continents (~ 1–2 ppb in winter, mostly due to model underestimation; Figs. 22 and 23). The averaged observed concentration of SO_2 is 1.92 and 2.7 ppb in EU and NA, respectively.

The seasonal modeled error for SO_2 ranges, on average, between 0.65 and 1.3 ppb in EU and between in excess of ~ 1 and 5 ppb in NA (the maximum error in NA2), peaking in autumn.

In EU and NA1, the error of the ID, DU, and SY components is comparable for all seasons and is, on average, below 0.6 ppb. There are some exceptions, most notably the WRF-CMAQ3 model, which is the only one biased significantly high (Fig. 23a) and it shows an excess of variance significantly larger than the other models. By contrast, WRF-Chem2, CHIMERE, and LOTOS-EUROS shows significant low bias (the latter two models have the smallest number of vertical layers). Overall, though, the bias error does not group consistently by PBL scheme and/or vertical resolution. For example, CMAQ2, CMAQ3, and CMAQ4 employ the same PBL scheme based on ACM2 and have a comparable number of vertical levels (CMAQ3 has even more), but the bias of CMAQ3 is much larger than that of CMAQ4 and CMAQ2, which in turn have comparable bias but opposite in sign. The two instances of WRF-Chem show significantly different bias, which might be due to the different PBL and cloud schemes, influencing the SO_2 oxidation (Table 2).

The large variability of the model-to-model error (especially in EU) and correlation coefficient for both continents is an indication that the mechanisms governing the initial mixing and subsequent transport and chemical transformation suffer from different sources of error at all scales. In no instance is the correlation coefficient consistently above 0.5 for all seasons and spectral components, while there are several instances of negative correlation between the spectral components of observed and modeled SO_2 (e.g., CCLM-CMAQ model in EU and several others). The poor correlation coefficient of especially the ID and DU components for both continents indicates that the peaks of the SO_2 concentration are not caught by the models, leading to low precision. Although the mean fluctuations are generally well reproduced (low variance error for both continents), there remains a significant portion of unexplained variance (mMSE) error, which can derive from meteorology and chemistry. Bieser et al. (2011b) showed that the height of the release and vertical distribution of the SO_2 emissions influence the SO_2 / SO_4 ra-
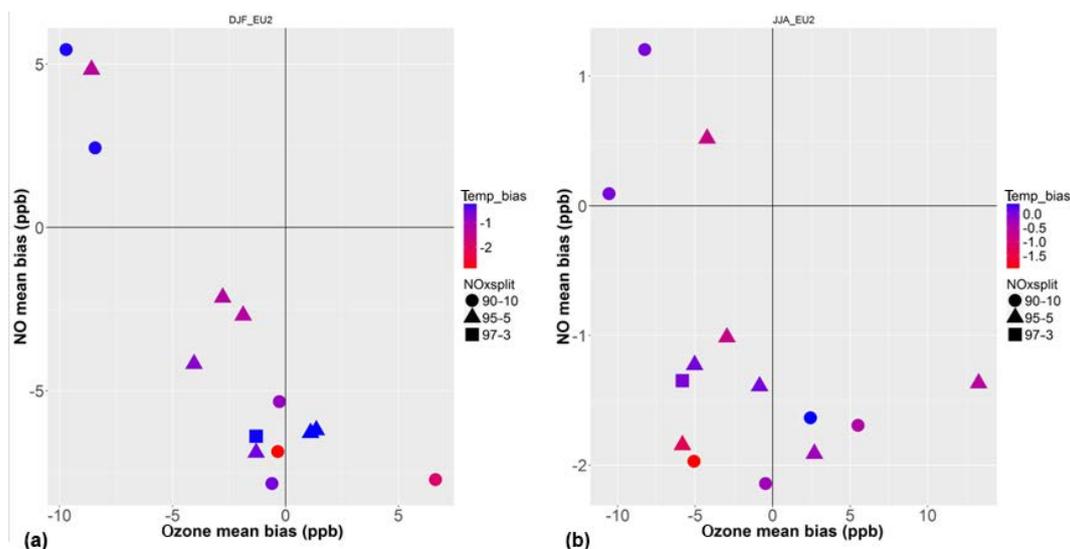

Figure 21. Ozone vs. NO modeled mean bias for the EU2 subregion, color-coded by temperature bias and symbols according to the NO$_x$ emission fraction of NO and NO$_2$. Each point represents a model. **(a)** Winter months and **(b)** summer months.

tio since the oxidation (aging) of SO$_2$ is more effective if the emissions are higher up. Since power plants are the major source of SO$_2$, further analysis should investigate the impact of differences in the vertical emission distribution between models.

3.3.10 Particulate matter

PM, in both the fine and coarse fraction, is directly emitted by biomass and fossil fuel combustion in domestic and industrial activities, and it is also formed from precursors in the atmosphere.

From the AQMEII3 suite of model runs, the error for PM is evaluated for PM$_{10}$ in EU and PM$_{2.5}$ in NA. The choice is dictated by the availability of hourly measurements in the two continents. The RMSE distribution is reported in Fig. 24 (PM$_{10}$ for EU) and Fig. 25 (PM$_{2.5}$ for NA). The error distribution for EU reveals that despite the large number of modeling options and parameters characterizing the chemistry and physics of particles, the error distribution for DU and SY is homogeneous among the EU models. For these components the error is approximately uniform over seasons, although with some exceptions (it is significantly higher in EU3, although this is based on two receptors only). EU3 is a small area compared to EU1 and EU2, but it is densely populated, intensively farmed, and has a large amount of wood burning in winter and agricultural area in summer. It is surrounded by mountains and stagnant flow conditions are predominant. Thus, it is a challenging area for current modeling systems, especially for primary species such as PM.

The LT component shows some significant model-to-model variations due to the WRF-CAMx and WRF-CMAQ1 models, which have a lower error in spring and summer com-

pared to the other models, while the CCLM-CMAQ model has a higher LT error in EU1.

The magnitude of the SY error in EU is on average $\sim 6\,\mu g\,m^{-3}$ during winter, with a peak of $10.5\,\mu g\,m^{-3}$ in EU2 (WRF-CAMx model). The magnitude of the DU error is lower (~ 2–$2.5\,\mu g\,m^{-3}$ in EU1 and EU2, and ~ 5–$6\,\mu g\,m^{-3}$ in EU3), with the largest share in autumn, spring, and winter and slightly lower in summer. The error of the LT component ranges between ~ 11 and $15\,\mu g\,m^{-3}$ in EU1 and EU2 and up to $25\,\mu g\,m^{-3}$ during winter in EU3.

The analysis of the correlation coefficient reveals that the model-to-model differences in the correlation coefficient with the observed component time series tend to be most pronounced for the DU and ID components, indicating that these two components are pivotal in determining the overall model skill in terms of capturing observed fluctuations in PM$_{10}$ concentration. In more detail, the correlation is poor for the DU component (especially in EU2 and EU3, Table S9), possibly due to PBL dynamics and emission profiles (as discussed above for the RMSE at the DU scale). The LT component has correlation values varying highly among models and among seasons for the same model (e.g., the LT correlation of the WRF-CMAQ4 model in EU3 is ~ 0.9 during spring but only 0.35 in summer).

In winter the LT and SY error is more severe, likely due to the larger uncertainties in PM$_{10}$ emissions of combustion processes (wood burning, residential heating), as well as due to the current limitations in modeling the vertical mixing during stable conditions, as mentioned for the gaseous species (especially CO, being another primary species). The majority of the EU models show an LT error in winter between 12 and $16\,\mu g\,m^{-3}$, eight models above $16\,\mu g\,m^{-3}$, and only one (WRF-CAMx) below $10\,\mu g\,m^{-3}$. The absence of background
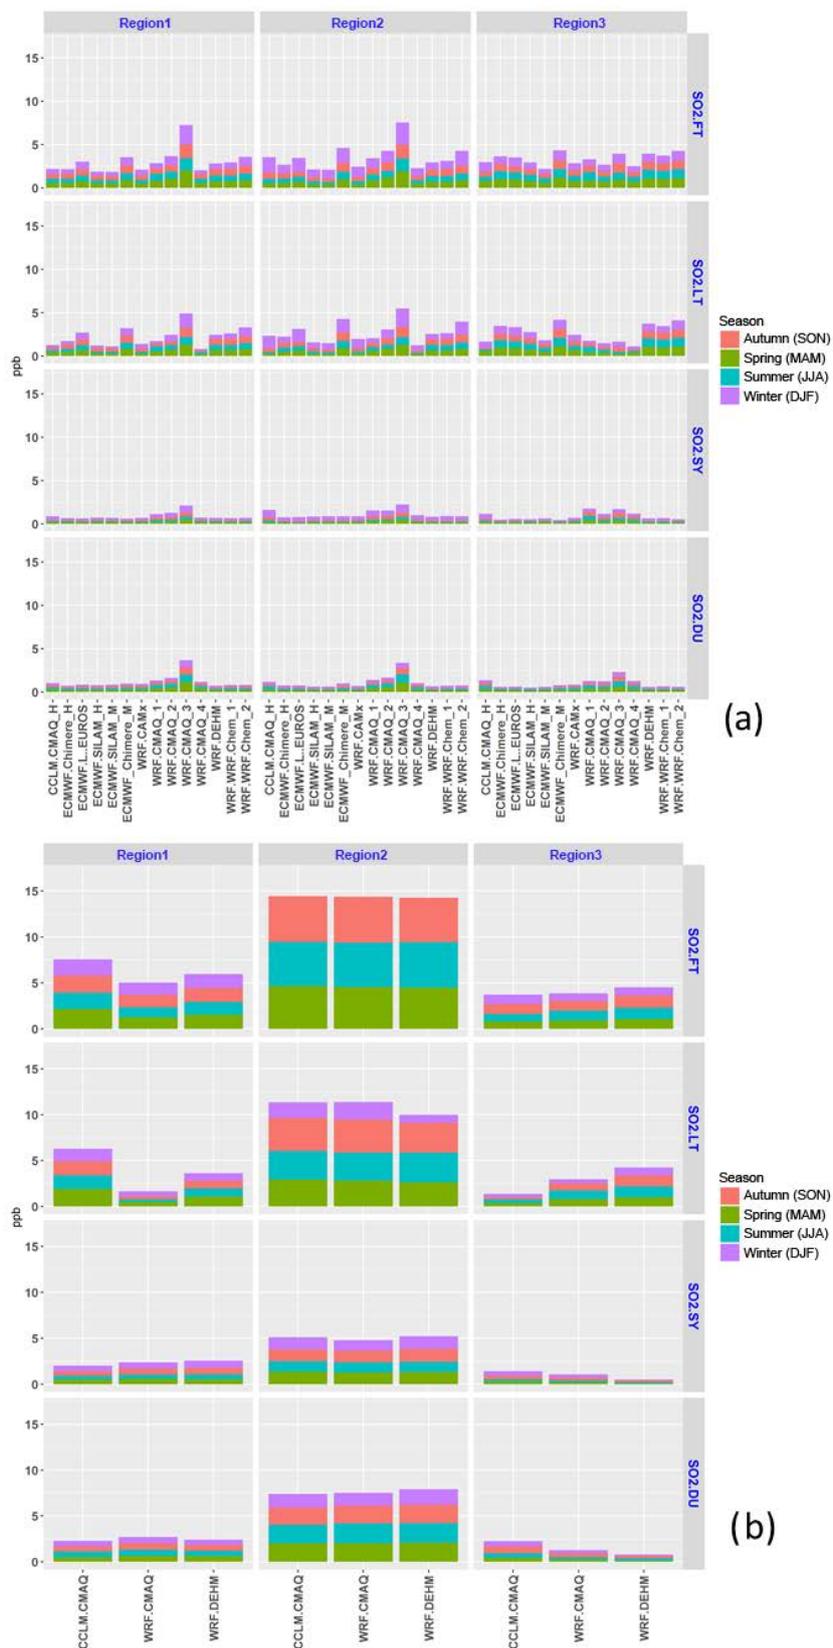

**Figure 22.** As in Fig. 9 but for SO$_2$.

Figure 23. As in Fig. 10 but for SO_2.

sea salt for all EU models (see end of Sect. 2.3) can also be responsible for low bias of the LT component for PM_{10}, especially in the vicinity of the coastline.

The SY winter error exceeds $5 \, \mu g \, m^{-3}$ for all models (all subregions) and three instances (WRF-CAMx, WRF-Chem1, and WRF-Chem2, the latter showing the highest accumulated deposition for $PM_{2.5}$; Fig. S11) report an error above $7.5 \, \mu g \, m^{-3}$, possibly due to the low nitrate concentration and high sulfate concentration during winter months, resulting from the GOCART parameterization of the aqueous cloud chemistry. All the remaining models have comparable mMSE and variance errors (Fig. 26) and are biased low (model underprediction), possibly due to missing PM source and overestimated surface wind speed. As for the WRF-CAMx model, the low bias on the LT component and the relatively high mMSE error in the SY fraction suggest that the model was able to capture the mean magnitude of PM con-

centration over the entire year, but it failed in reconstructing the correct variability of the different episodes, whose timing is generally driven by the synoptic timescale.

The analysis of corr ($bias_{Temp}$, $bias_{PM_{10}}$)$_{LT}$ shows that the error of these two variables is related, especially during the spring months and more consistently in EU3 (up to 0.74 for the WRF-Chem1 model) and during autumn in EU1 (the bias of temperature and the bias of PM_{10} are anticorrelated up to -0.67 for CMAQ1). Conversely, other models (e.g., the CAMx model) do not show any significant correlation.

The $PM_{2.5}$ evaluation for NA is restricted to two models, WRF-DEHM and WRF-CMAQ, which show comparable error (Fig. 25). The WRF-CMAQ (WRF-DEHM) model has an error ranging between ~ 3.5 (~ 2) and ~ 6 (~ 8.5) $\mu g \, m^{-3}$. The main contribution to the total error stems from the LT component (predominantly negative bias) and from the SY
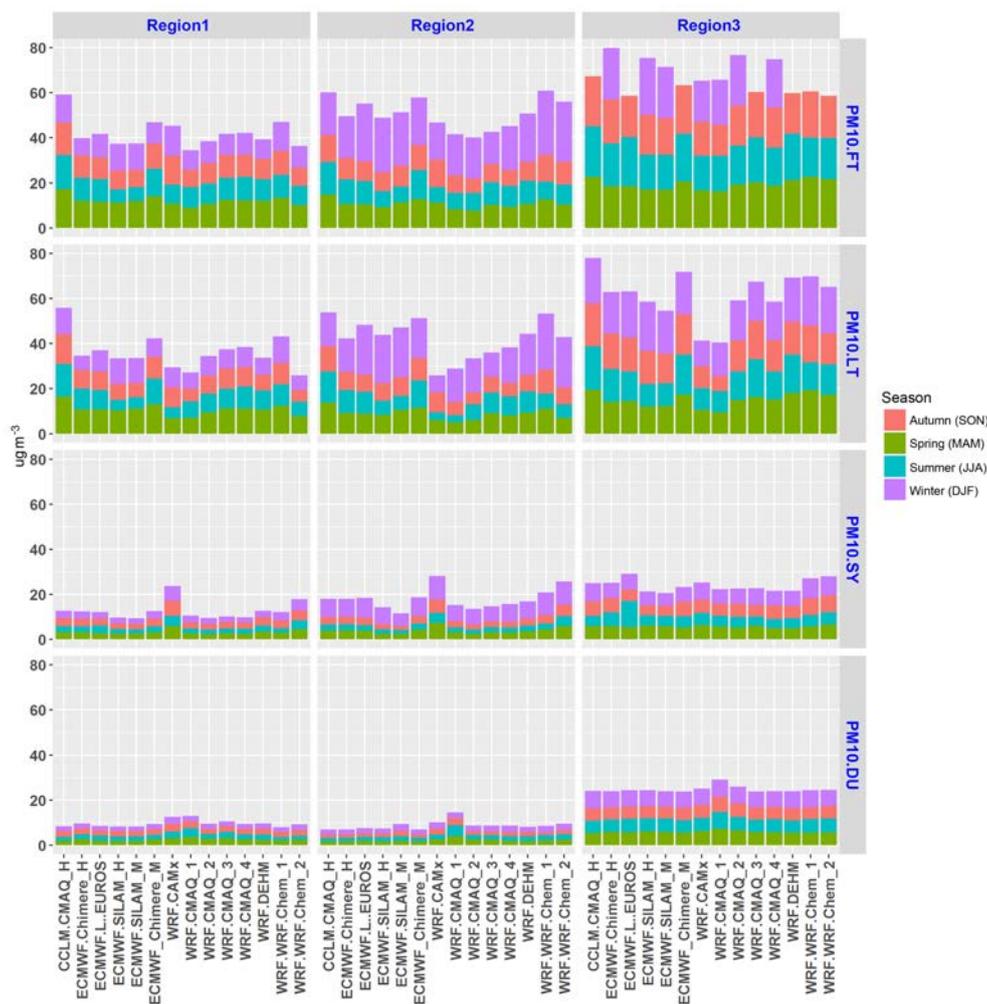

Figure 24. As in Fig. 9 but for PM$_{10}$ in Europe (error units in µg m^{-3}).

component (2–3 µg m^{-3}). The DU component contributes to about 1.5 µg m^{-3} (comparable mMSE and variance error).

Both NA models are biased low in summer (all subregions), which can be attributed to limitations in the SOA mechanism (Zare et al., 2014). Because of the higher contribution of primary PM$_{2.5}$ to total PM$_{2.5}$ during winter, differences in horizontal and vertical resolution (Table 1) likely contribute to the difference in winter LT bias. The correlation coefficient for the two models is generally higher in winter (full time series) and deteriorated for the DU component (all seasons and subregions).

As inferred for the species discussed above, the uniformity of model behavior is indicative of errors stemming from external fields, likely emissions, where missing sources of PM can affect the error within certain timescales for all models. Further common causes of error are intrinsic to the model–observation comparison because modeled PMs are commonly dry, while this is not always the condition for the measurements. For instance, the filter-based gravimet-

ric measurements as recommended by the European Committee for Standardization (CEN) are likely to retain part of the particle-bound water after filter conditioning at a constant temperature of 20 °C and relative humidity of 50 %. Recent findings by Prank et al. (2016) report the aerosol water content from the gravimetric measurements to range between 5 and 20 % for PM$_{2.5}$ and between 10 and 25 % for PM$_{10}$. The particle-bound water was found to be associated with hygroscopic particles such as sulfate, nitrate, and organic compounds. This remaining water content can be up to approximately 10–35 % depending on the chemical composition of aerosols being measured (Tsyro, 2005; Kajino et al., 2006; Jones and Harrison, 2006). The water aerosols should therefore be accounted for when compared with these measurements. Part of the problem lies in secondary organic aerosol. In winter, in particular for the wood burning part of the emissions, there are condensable gases that rapidly change to the aerosol phase but are missed since they are not part of the presently used PM emission inventory. In summer, biogenic
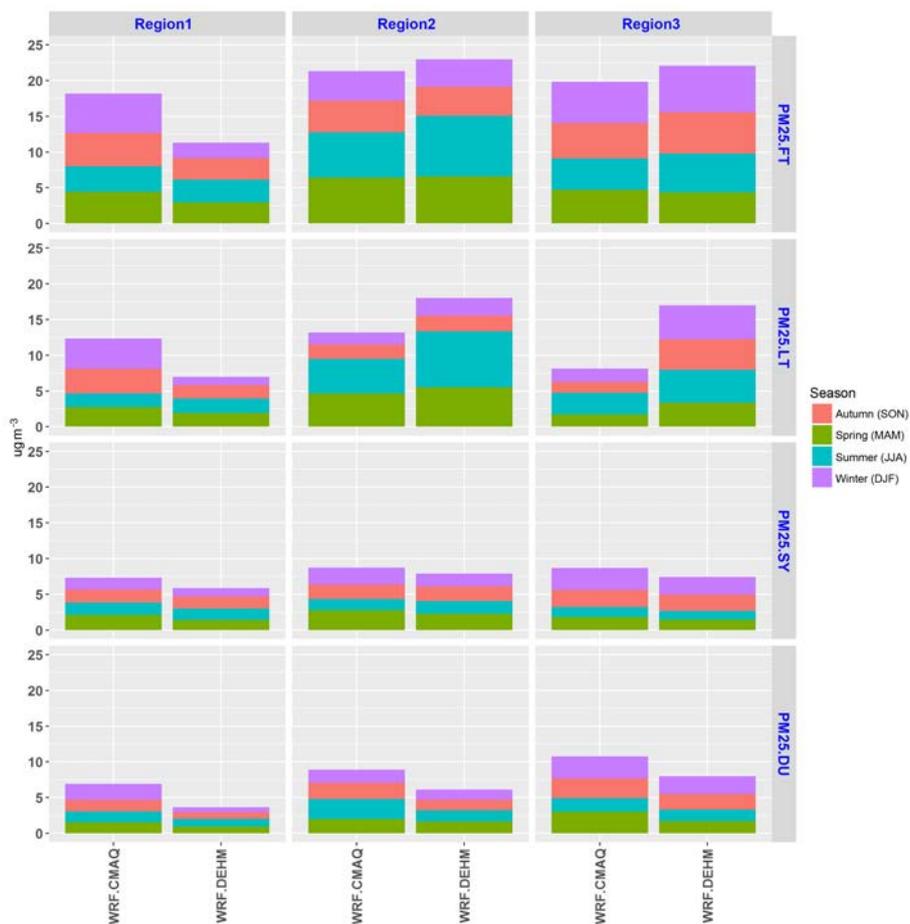

Figure 25. As in Fig. 9 but for $PM_{2.5}$ in North America (error units in $\mu g\, m^{-3}$).

**Figure 26.** As in Fig. 10 but for PM_{10} in Europe (error units in $\mu g\, m^{-3}$).

**Figure 27.** As in Fig. 10 but for PM$_{2.5}$ in North America (error units in µg m^{-3}).

emissions that contribute to SOA formation and their yields are quite uncertain. A good representation of SOA is still a problem for all models. In spring, the application of manure and fertilizer leads to peaks of NH$_3$ emissions and subsequent NH$_4$ aerosol formation, contributing to PM$_{10}$ and PM$_{2.5}$. The timing of these emissions is parameterized based on long-time averages, whereas in practice they are strongly related to meteorology. This can explain part of the discrepancy between the diurnal and synoptic timescales (Hendriks et al., 2016).

4 Memory of the signal and removal processes: the case of ozone

The evaluation of the removal processes (chemical transformation, transport, and deposition) is difficult to assess in isolation with respect to other sources of error because of the bias of the signal. In this section we propose a bias-independent spatial analysis aimed at the quantification of the memory of the signal. The analysis seeks the time interval (or memory) after which the signal loses any memory of its past. The memory of the modeled and observed signals is then compared. The methodology consists of

1. calculating the autocorrelation function (acf) of the modeled and observed LT components;

2. calculating the quantity acf$_{mod=0}$ and acf$_{obs=0}$, i.e., the lag (time interval) where the acf of the modeled and observed LT components falls to zero; and finally

3. determining the difference between the two, which yields the difference between the modeled and observed memory of the signal:

$$\Delta_{\text{memory}} = \text{acf}_{\text{mod}=0} - \text{acf}_{\text{obs}=0}. \quad (9)$$

The acf is simply a measure of the degree of associativity of a time series with its lagged version. The associativity is typically measured through the correlation coefficient, and the lag extends from one time step (1 h in the case of hourly time series) to one-third of the length of the time series. Because the correlation is bias-independent, we conclude that the acf is also bias-independent; therefore, information from Δ_{memory} is useful for the interpretation of the variance and covariance errors discussed in Sect. 3.1. The memory of the signal is different from the persistence indicator (previous day concentration) as used by Otero et al. (2016), for example, for accounting for pollutant episodes. As we deal with the LT component of the signal, short-term and synoptic episodes are in fact filtered out in this analysis.

In Figs. S9 and S10, the acf for the network-wide spatial average and for the full year are reported. The acf is calculated for the LT component of the observed (first panel) and modeled ozone time series. The zero of the acf and the slope of the decay of acf of the observations (approximately a straight line from 1 to 0 in 2000 h) are replicated by the models with various degree of success (Fig. S10). Our intent is to apply this analysis to the seasonal ozone time series at each receptor and derive useful information about the modeled removal–production processes. The spatial analysis is proposed for ozone for the months of May to September (Figs. 28 and 29) and for the full year (Figs. S9 and S10).

The average lifetime of ozone in the troposphere is of approximately 20–30 days (Solomon et al., 2007). By analyzing the LT component (processes > ∼ 21 days), we therefore screen out the daily removal–transformation due to chemistry and can focus on seasonal transport, deposition of the free tropospheric ozone, long-term chemistry (seasonal changes in vegetation that affect biogenic VOC emissions and ozone deposition, and also the monthly variations applied to the anthropogenic emission), and influence of boundary condi-
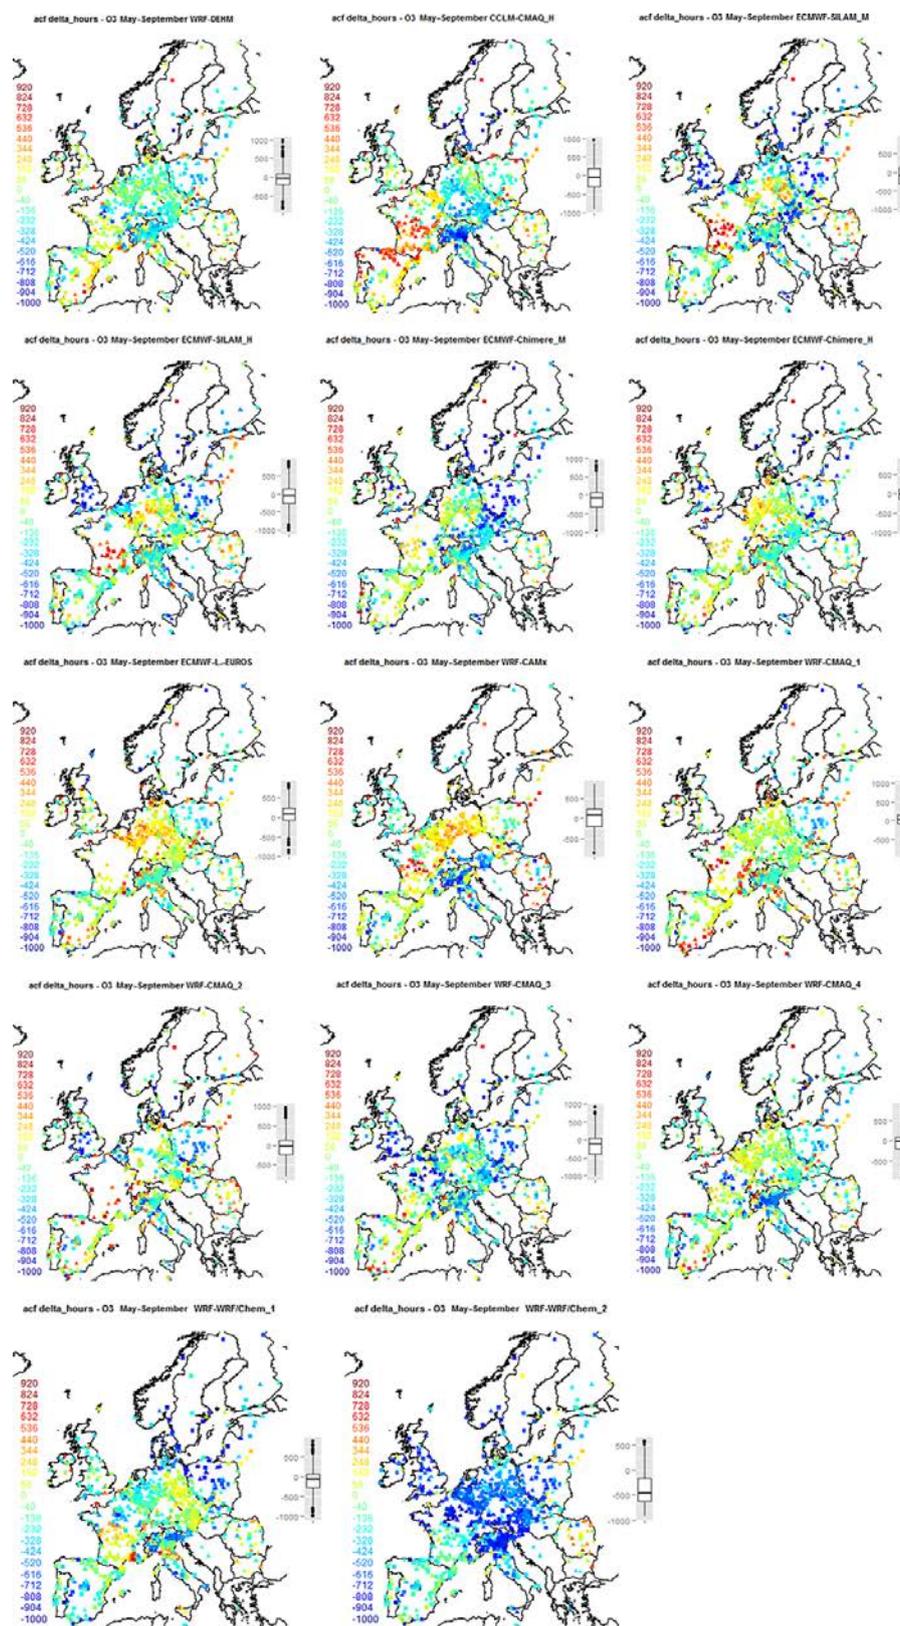

Figure 28. Spatial map of the ozone monitoring stations colored based on the "delta hour" values, i.e., the difference in hours between the zero of the autocorrelation function (acf) for the modeled ozone minus the zero of the acf of the observed one. The acf is calculated on the long-term component for the months of May to September. Negative values indicate too-short memory and excess of removal (vice versa for positive values). The box on the right summarizes the delta hour percentile distribution.

tions. The structure of the acf also benefits from the removal of short timescale processes because it is less affected by noise and the results are easier to interpret.

The spatially distributed Δ_{memory} shows some clear regional effects for the majority of the models. The $\Delta_{memory} > 0$ along the Mediterranean coast of Spain and France, with some severe excess of ozone production (or underestimation of sinks) in southern-central France for some models (SILAM, WRF-CAMx, WRF-CMAQ1, WRF-CMAQ2, and especially the LOTOS-EUROS model, for which the acf at the French receptors did not reach zero).

The region covering the Po Valley, Italy, and extending into continental eastern EU is affected by negative Δ_{memory} (sometimes a deficit of 1 month for some models). The negative memory indicates that the observed signal is more persistent than the modeled one and that long-term weather transitions are smoother in gradient and longer in duration. Thus, the seasonal modulation of the signal is overestimated by the models, which produces variance error. Coupling the two behaviors (excess of ozone in southern France and southern Spain with the short memory from the interior of eastern EU extending to the Po Valley) might indicate an easterly synoptic transport of ozone (or of LT ozone precursor, such as the impact of CH_4 and CO on OH and photochemistry) masses whose duration is underestimated by the models. The relationship between the sign of Δ_{memory} and the land use type (vegetation vs. urban) is the subject of ongoing investigations in the attempt to determine the role of VOC emissions and deposition over different land types.

The central part of Germany is affected by positive (on average in the range of 7 to 10 days) Δ_{memory}, mostly visible for the HTAP-emission-based SILAM and CHIMERE results, in contrast with the MACC-emission-based results of the same models. When the HTAP inventory is used, the largest differences are observed in central EU regions, indicating that the LT chemistry also plays a role.

The deposition aspect of removal can be as equally important as transport and chemistry. The memory of the signal directly depends on the amount of ozone available and a large negative Δ_{memory} might indicate that the deposition is too high.

For NA (Fig. 29), the feature common to all models is the excess of removal on the southern Atlantic coast and across the eastern Canadian border. In contrast, the central-eastern part of the US shows large positive Δ_{memory} values (up to ~ 1.3 month for the WRF-DEHM model), with the exception of the WRF-CMAQ model, which is overall in line with the observed memory of the signal in this part of the domain. This result agrees with the seasonal phase analysis for ozone in global models by Bowdalo et al. (2016), where a delay of up to 4 months was detected for the eastern US.

The west coast has a mixed behavior, but Δ_{memory} is prevalently negative. The hypothesis that too little ozone enters the domain through the boundary conditions is contradicted by the $\Delta_{memory} \sim 0$ for a full year on the west coast (see Fig. S10). A potential excess of transport in this region also seems to be contradicted by the large number of stations for which Δ_{memory} is positive. A possible conclusion is that localized biogenic emission sources, radiation budget, and deposition are the main factors responsible for the negative sign of Δ_{memory} in this region.

5 Conclusions

The work presented in this paper summarizes the results of the third phase of the AQMEII activity focusing on AQ model evaluation, applied to the continental-scale domains of Europe and North America. The evaluation of the AQMEII3 suite of model runs is carried out for surface temperature, wind speed, and direction and for the species CO, NO, NO_2, ozone, SO_2, PM_{10} (EU), and $PM_{2.5}$ (NA). Additional analyses making use of emission reduction scenarios (CO and NO) and vertical profiles were also performed.

This work is primarily meant to provide a wide overview of the performance of current regional AQ modeling systems and to set the basis for additional diagnostic analysis that is currently in progress.

The model evaluation is carried out by quantifying the components of the error (bias, variance, mMSE) at four timescales (ID, DU, SY, LT), each describing physical processes in a specific time range. The bias and variance measure the departure from the first and second moment of the observed distribution (mean and standard deviation), while the mMSE accounts for the unexplained observed variability. The apportionment of the error to the relevant timescales and the analysis of the quality of the error revealed that the LT bias is by far the biggest cause of error, followed by the variance error (fluctuations about the mean value) of the DU component and the unexplained variance of the DU and SY components, depending on the species and season. In more detail:

- The mean concentration of the primary species (NO, CO, PM_{10}, SO_2) is underestimated by the vast majority of the models on both continents, more markedly during the winter and autumn seasons. The largest share of error for these species is the bias of the LT components, most probably due to error of the fluxes at the boundaries (emission, deposition, and boundary conditions) and to the effects of comparing point measurements to volume-averaged concentrations.

- The bias is by far the primary source of error and the most important from a model evaluation–development point of view. Because it is essentially a shift of the mean concentration, the causes of it need to be sought in processes and conditions at the boundaries that have a systematic effect of displacing the concentration values while approximately preserving the shape of the distribution. Thus, processes like emission timing, chemistry
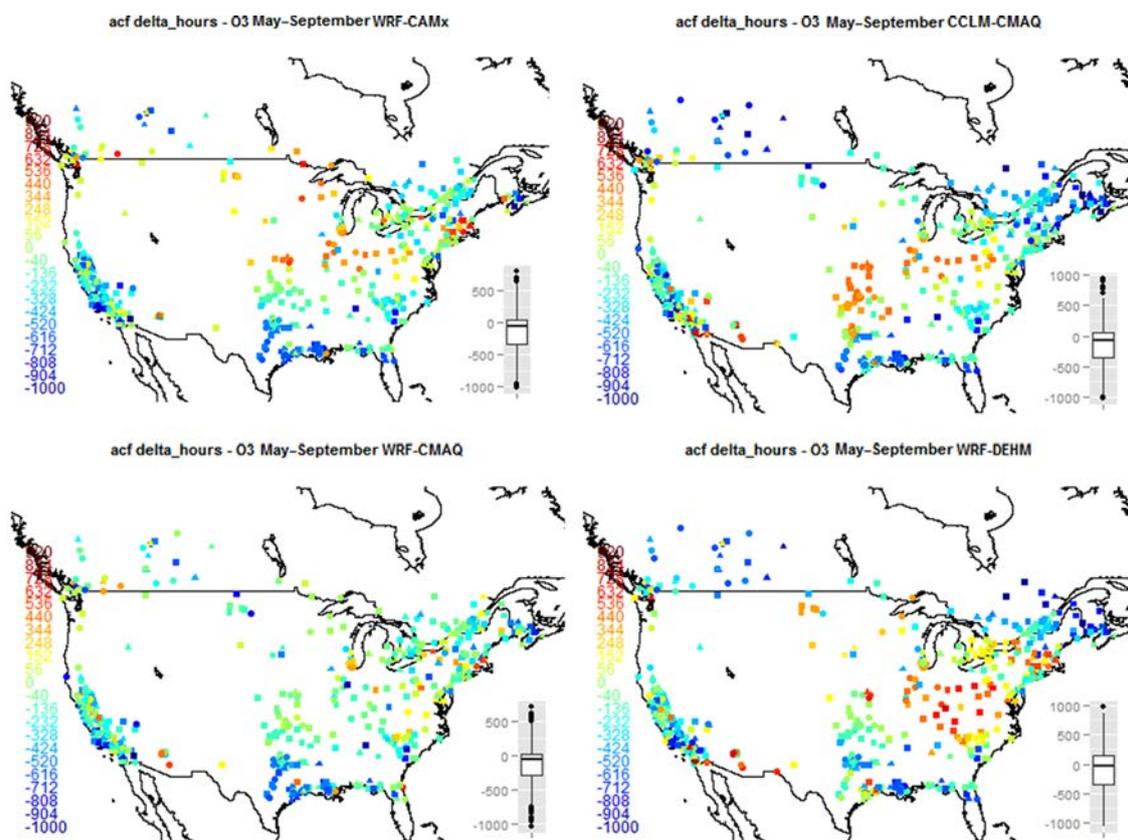

Figure 29. As in Fig. 28 but for North America.

transformation, autocorrelation structures, stratospheric intrusion, and atmospheric stability are not likely responsible for systematic bias-type error (though they can be a source of casual inaccuracy for limited periods). Conversely, deposition fluxes, magnitude of emission, and input from the lateral boundaries are more probable sources of bias error. The effect of meteorology is more complex because errors in synoptic circulation can cause surface wind velocity and direction to be inaccurate, and thus negatively impact the long-term modeled concentrations, causing bias error.

– The meteorological fields of temperature and wind speed are consistently biased low and high, respectively. Based on the results of the European models directly driven by the global fields for meteorology (e.g., SILAM, CHIMERE), the error for wind speed is of ~ 0.5–$1\,\mathrm{m\,s^{-1}}$ and of ~ 0.4–$1.2\,\mathrm{K}$ for temperature. These errors can be considered as the uppermost limit the accuracy of the models can currently achieve. The use of nudging and interpolation methods (specific to the configuration of the meteorological model) can add more than $1.5\,\mathrm{K}$ and $2\,\mathrm{m\,s^{-1}}$ to the total error. The analysis of the available vertical profiles suggests that the models overestimate the wind speed within the PBL and

vice versa above the PBL, possibly inducing a net outward flux of pollutants at the PBL interface.

– Modeled CO is affected by high errors, uniformly across models and components and more pronounced in winter. It is also predominantly driven by the negative bias of the LT component, followed by variance error of the SY component. Modeled NO and NO_2 also report negative bias but in contrast to CO, there is significant model-to-model difference in error variability, possibly due to the chemistry of NO_x. The SY and DU errors of NO are comparable in magnitude (3–5 ppb) and mostly due to mMSE error. Preliminary sensitivity investigations for CO and NO seem to suggest that at most ~ 50 and $\sim 35\,\%$ of the total error, respectively, could be due to emissions.

– The error analysis for ozone shows large model-to-model variability for all errors and spectral components, with the exception of the SY component for which the error is similar among models and possibly driven by the error in temperature and in the boundary conditions. This is because modeled vertical ozone profiles near the domain's boundaries are typically underestimated in both continents by all models. The bias is prevalently positive, while the variance error is generally small.

While the bias error for ozone is likely driven by error in NO_x emissions, the error in meteorology may factor in determining the mMSE and variance error. In fact, there are several models for which the bias of temperature and the bias of NO_2 are strongly associated with the DU error of ozone. A simple linear regression between NO_x bias and ozone bias (based on the yearly time series) among the EU models suggests that the NO_x and temperature biases can explain, on average, ~ 35 and $\sim 16\%$ of the variability of the ozone bias, respectively. Ongoing analyses are focusing on explaining the origin of the mMSE error by investigating the phase shift between the modeled and observed DU and SY components as well as focusing on looking at maximum daily values rather than at the full time series.

– PM analysis (PM_{10} for Europe and $PM_{2.5}$ for North America) reveals that for Europe the error distribution for DU and SY is homogeneous and season independent among the models, despite the large numbers of modeling options and parameters characterizing the chemistry and physics of particles. A common source of model bias (model underestimation, especially in winter) for PM_{10} likely lies in the emissions (missing sources) and in the overestimation of surface wind speed, whereas variance error may stem from PBL dynamics under stable conditions and missing processes in the model (SOA formation is a known issue for all models). The analysis of $PM_{2.5}$ (based on two models only) shows an excess of variance and low correlation coefficient in the DU component, possibly due to the timing of the PM cycle. Further analyses dealing with the PM components are needed.

– The analysis of the memory of the ozone signal has revealed a strong model deficit in continental Europe, where the seasonal modulation of ozone is overestimated by the majority of the models. The opposite holds true in the continental US.

Although remarkable progress has been made since the first phase of AQMEII, both in terms of model performance and in terms of developing a more versatile and robust evaluation procedure, results of AQ model evaluation and intercomparison remain generic since they fail to associate errors with processes, or at least to narrow down the list of processes responsible for model error. AQ models are meant to be applicable to a variety of geographic (and topographic) scenarios under almost any type of weather, season, and emission conditions. For such a wide range of conditions the inherent nonlinearity among processes is difficult to disentangle, and specifically designed sensitivity runs seems to be the only viable alternative. A model evaluation strategy relying solely on the comparison of modeled vs. observed time series would never be able to quantify exactly the error induced by biogenic emissions, vertical emission profiles,

or their dependence on temperature, deposition, and vertical mixing, for example, and the analyses presented in this work are no exception. In fact, the methodology devised to carry out the evaluation activity in this study has not succeeded in determining the actual causes of model error, although it does provide much clearer indications of the processes responsible for the error with respect to conventional operational model evaluation.

The highly nonlinear nature of current AQ models requires the study of the relationships among error fields, meteorological drivers, and precursors. When the seasonal and spectral structures of these relationships are analyzed together with the error of the input fields (emissions and boundary conditions), then it would be possible to diagnose and accurately explain the processes responsible for the error. Future AQ model evaluation activities should envision sensitivity simulations and process specific analyses. The "theory of evaluation" based on information theory currently being developed by the hydrology modeling community (Nearing et al., 2016, and references therein) is a promising way forward and the AQ community should be prepared for those developments.

Ongoing work (Solazzo et al., 2017) is being devoted to deepening the investigation into causes of model errors by focusing on two models (CMAQ for NA and CHIMERE for EU), for which additional model runs were carried out to frame the effect of fluxes (emissions, boundary conditions, and deposition) on modeled ozone.

6 Data availability

The modeling and observational data generated for the AQMEII exercise are accessible through the ENSEMBLE data platform (http://ensemble3.jrc.it/) upon contact with the managing organizations. References to the repositories of the observational data used have been also provided in Sect. 2.3.2.

Appendix A

Following Hogrefe et al. (2000) and Galmarini et al. (2013), the time windows (m) and the smoothing parameter (k) were selected as follow:

$$
\begin{aligned}
\mathrm{ID}(t) &= \boldsymbol{x}(t) - \mathrm{kz}_{3,3}(\boldsymbol{x}(t)) \\
\mathrm{DU}(t) &= \mathrm{kz}_{3,3}(\boldsymbol{x}(t)) - \mathrm{kz}_{13,5}(\boldsymbol{x}(t)) \\
\mathrm{SY}(t) &= \mathrm{kz}_{13,5}(\boldsymbol{x}(t)) - \mathrm{kz}_{103,5}(\boldsymbol{x}(t)) \\
\mathrm{LT}(t) &= \mathrm{kz}_{103,5}(\boldsymbol{x}(t)) \\
\boldsymbol{x}(t) &= \mathrm{ID}(t) + \mathrm{DU}(t) + \mathrm{SY}(t) + \mathrm{LT}(t),
\end{aligned} \tag{A1}
$$

where $\boldsymbol{x}(t)$ is the time series vector. The additive property of the components whose summation returns the original time series might be questioned. In the original work by Rao et al. (1997) the importance of log-transforming the components to stabilize the variance is highlighted. In the case of log-transformation, the original time series is obtained by the product of exponential functions whose exponents are the spectral components. For the purposes of the error apportionment analysis presented here, the results of using the additive time series component of log-transformation did not produce substantial differences.

A clear-cut separation of the components of Eq. (A1) is not achievable since the separation is a nonlinear function of the parameters m and k (Rao et al., 1997). It follows that the components of Eq. (A1) are not completely orthogonal and that there is some level of overlapping energy (Kang et al., 2013). Galmarini et al. (2013) found that the explained variance by the spectral components accounts for 75 to 80 % of the total variance, the remaining portion coming from the interactions between the components.

Appendix B

Statistical indicators are as follows:
    root mean square error as

$$
\mathrm{RMSE} = \left(\frac{\sum_{i=1}^{n}(M_i - O_i)^2}{n} \right)^{0.5},
$$

mean bias (MB) as

$$
\mathrm{MB} = \frac{1}{n}\sum_{i=1}^{n} M_i - O_i,
$$

and Pearson correlation coefficient (r) as

$$
r = \frac{1}{n-1}\sum_{i=1}^{n} \left(\frac{M_i - \overline{M}}{\sigma_M} \right)\left(\frac{O_i - \overline{O}}{\sigma_O} \right),
$$

where M and O are the n element-modeled and -observed time series, respectively, σ is the standard deviation, and the overbar indicates temporal averaging.
